## Clusters & Other Low-Dimensional Structure 10716: Probabilistic Graphical Models Pradeep Ravikumar (amending notes from Larry Wasserman)

## 1 Estimating Low Dimensional Structure

Let  $X_1, \ldots, X_n \sim P$ . We are interested in extracting "low dimensional structure" in P. This comprises pretty much of all of what we term as "unsupervised learning" aside from density/distribution estimation, where we estimate the distribution P itself.

We can think of the structure we are looking for as a function of P. Examples of such functions include:

T(P) = clusters of P

T(P) = the support of P

T(P) = dimension of the support

T(P) = ridges of the density p

T(P) = DTM (distance to a measure)

## 2 The Clustering Problem

Of the various instances of low-dimensional structure, the most popular is clusters of P. It could be because this has the most applications. Or perhaps because statistically this is the most feasible.

In a clustering problem we aim to extract partitions of the input space  $\mathcal{X}$  as informed by P. This is vague, and indeed, there are many ways to formalize this, and hence many different clustering methods. But all of them give us a partition of the input space. Many algorithms in ML work with the empirical distribution  $\mathbb{P}_n$  over the samples  $\{X_i\}_{i=1}^n$  and output groups over these samples rather than a partition over the input space. But here, we are concerned with the broader estimation task of recovering the target partition of  $\mathcal{X}$  itself, given P. Note that classification also aims to find a partition over  $\mathcal{X}$ , with each element of the partition corresponding to one of a discrete set of labels, but unlike classification here, the data are not labeled, and so clustering is an example of unsupervised learning.

We will study the following approaches, each of which corresponds to a different notion of the target "partition":

- 1. k-means
- 2. Mixture models
- 3. Density-based Clustering, and the related Hierarchical Clustering

There are other notions such as mode clustering and spectral clustering, but these can also be looked at as extracting other notions of structure, and representation learning, which we will study in the sequel.

**Example 1** Figures 20 and 21 show some synthetic examples where the clusters are meant to be intuitively clear. In Figure 20 there are two blob-like clusters. Identifying clusters like this is easy. Figure 21 shows four clusters: a blob, two rings and a half ring. Identifying clusters with unusual shapes like this is not quite as easy. In fact, finding clusters of this type requires nonparametric methods.

# 3 k-means (Vector Quantization)

One of the oldest approaches to clustering is to find k representative points, called *prototypes* or *cluster centers*, and then divide the data into groups based on which prototype they are closest to. For now, we assume that k is given. Later we discuss how to choose k.

**Warning!** My view is that k is a tuning parameter; it is **not** the number of clusters. Usually we want to choose k to be larger than the number of clusters.

Let  $X_1, \ldots, X_n \sim P$  where  $X_i \in \mathbb{R}^d$ . Let  $C = \{c_1, \ldots, c_k\}$  where each  $c_j \in \mathbb{R}^d$ . We call C a codebook. Let  $\Pi_C[X]$  be the projection of X onto C:

$$\Pi_C[X] = \operatorname{argmin}_{c \in C} ||c - X||^2. \tag{1}$$

Define the empirical clustering risk of a codebook C by

$$R_n(C) = \frac{1}{n} \sum_{i=1}^n \left| \left| X_i - \Pi_C[X_i] \right| \right|^2 = \frac{1}{n} \sum_{i=1}^n \min_{1 \le j \le k} ||X_i - c_j||^2.$$
 (2)

Let  $C_k$  denote all codebooks of length k. The optimal codebook  $\widehat{C} = \{\widehat{c}_1, \dots, \widehat{c}_k\} \in C_k$  minimizes  $R_n(C)$ :

$$\widehat{C} = \operatorname{argmin}_{C \in \mathcal{C}_{l}} R_{n}(C). \tag{3}$$

The empirical risk is an estimate of the population clustering risk defined by

$$R(C) = \mathbb{E} \left| \left| X - \Pi_C[X] \right| \right|^2 = \mathbb{E} \min_{1 \le j \le k} ||X - c_j||^2$$
 (4)

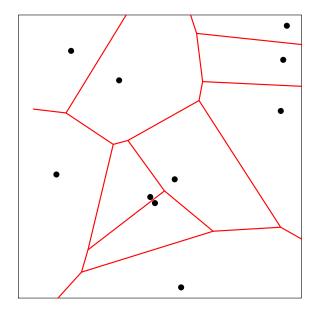

Figure 1: The Voronoi tesselation formed by 10 cluster centers  $c_1, \ldots, c_{10}$ . The cluster centers are indicated by dots. The corresponding Voronoi cells  $T_1, \ldots, T_{10}$  are defined as follows: a point x is in  $T_j$  if x is closer to  $c_j$  than  $c_i$  for  $i \neq j$ .

where  $X \sim P$ . The optimal population quantization  $C^* = \{c_1^*, \dots, c_k^*\} \in \mathcal{C}_k$  minimizes R(C). We can think of  $\widehat{C}$  as an estimate of  $C^*$ . This method is called k-means clustering or vector quantization.

A codebook  $C = \{c_1, \dots, c_k\}$  defines a set of cells known as a *Voronoi tesselation*. Let

$$V_j = \left\{ x : ||x - c_j|| \le ||x - c_s||, \text{ for all } s \ne j \right\}.$$
 (5)

The set  $V_j$  is known as a Voronoi cell and consists of all points closer to  $c_j$  than any other point in the codebook. See Figure 1.

The usual algorithm to minimize  $R_n(C)$  and find  $\widehat{C}$  is the k-means clustering algorithm—also known as Lloyd's algorithm—see Figure 2. The algorithm is an alternating optimization method applied to the following reformulation of the kmeans clustering objective:

$$\min_{C} R_n(C) = \min_{C} \frac{1}{n} \sum_{i=1}^{n} \min_{1 \le j \le k} ||X_i - c_j||^2$$

$$= \min_{C} \min_{g:[n] \mapsto [k]} \frac{1}{n} \sum_{i=1}^{n} ||X_i - c_{g(j)}||^2.$$

- 1. Choose k centers  $c_1, \ldots, c_k$  as starting values.
- 2. Form the clusters  $C_1, \ldots, C_k$  as follows. Let  $g = (g_1, \ldots, g_n)$  where  $g_i = \operatorname{argmin}_j ||X_i c_j||$ . Then  $C_j = \{X_i : g_i = j\}$ .
- 3. For j = 1, ..., k, let  $n_j$  denote the number of points in  $C_j$  and set

$$c_j \longleftarrow \frac{1}{n_j} \sum_{i: X_i \in C_j} X_i.$$

- 4. Repeat steps 2 and 3 until convergence.
- 5. Output: centers  $\widehat{C} = \{c_1, \dots, c_k\}$  and clusters  $C_1, \dots, C_k$ .

Figure 2: The k-means (Lloyd's) clustering algorithm.

The risk  $R_n(C)$  has multiple minima. The algorithm will only find a local minimum and the solution depends on the starting values. A common way to choose the starting values is to select k data points at random. We will discuss better methods for choosing starting values in Section 3.2.

**Example 2** Figure 3 shows synthetic data inspired by the Mickey Mouse example from http://en.wikipedia.org/wiki/K-means\_clustering. The data in the top left plot form three clearly defined clusters. k-means easily finds in the clusters (top right). The bottom shows the same example except that we now make the groups very unbalanced. The lack of balance causes k-means to produce a poor clustering. But note that, if we "overfit then merge" then there is no problem.

**Example 3** The top left plot of Figure 4 shows a dataset with two ring-shaped clusters. The remaining plots show the clusters obtained using k-means clustering with k = 2, 3, 4. Clearly, k-means does not capture the right structure in this case unless we overfit then merge.

## 3.1 Theoretical Properties

A theoretical property of the k-means method is given in the following result. Recall that  $C^* = \{c_1^*, \ldots, c_k^*\}$  minimizes  $R(C) = \mathbb{E}||X - \Pi_C[X]||^2$ .

**Theorem 4** Suppose that  $\mathbb{P}(||X_i||^2 \leq B) = 1$  for some  $B < \infty$ . Then

$$\mathbb{E}(R(\widehat{C})) - R(C^*) \le c\sqrt{\frac{k(d+1)\log n}{n}}$$
(6)

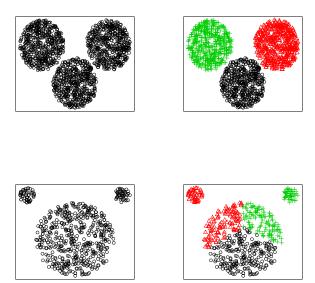

Figure 3: Synthetic data inspired by the "Mickey Mouse" example from wikipedia. Top left: three balanced clusters. Top right: result from running k means with k=3. Bottom left: three unbalanced clusters. Bottom right: result from running k means with k=3 on the unbalanced clusters. k-means does not work well here because the clusters are very unbalanced.

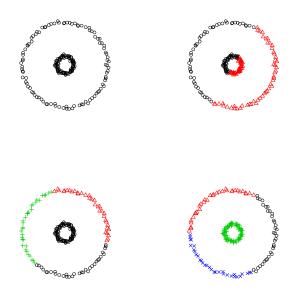

Figure 4: Top left: a dataset with two ring-shaped clusters. Top right: k-means with k=2. Bottom left: k-means with k=3. Bottom right: k-means with k=4.

for some c > 0.

**Warning!** The fact that  $R(\widehat{C})$  is close to  $R(C_*)$  does not imply that  $\widehat{C}$  is close to  $C_*$ .

This proof is due to Linder, Lugosi and Zeger (1994), and follows along standard VC theory techniques.

**Proof.** Note that  $R(\widehat{C}) - R(C^*) = R(\widehat{C}) - R_n(\widehat{C}) + R_n(\widehat{C}) - R(C^*) \le R(\widehat{C}) - R_n(\widehat{C}) + R_n(C^*) - R(C^*) \le 2 \sup_{C \in \mathcal{C}_k} |R(\widehat{C}) - R_n(\widehat{C})|$ . For each C define a function  $f_C$  by  $f_C(x) = ||x - \Pi_C[x]||^2$ . Note that  $\sup_x |f_C(x)| \le 4B$  for all C. Now, using the fact that  $\mathbb{E}(Y) = \int_0^\infty \mathbb{P}(Y \ge t) dt$  whenever  $Y \ge 0$ , we have

$$2 \sup_{C \in \mathcal{C}_k} |R(\widehat{C}) - R_n(\widehat{C})| = 2 \sup_{C} \left| \frac{1}{n} \sum_{i=1}^n f_C(X_i) - \mathbb{E}(f_C(X)) \right|$$

$$= 2 \sup_{C} \left| \int_0^\infty \left( \frac{1}{n} \sum_{i=1}^n I(f_C(X_i) > u) - \mathbb{P}(f_C(Z) > u) \right) du \right|$$

$$\leq 8B \sup_{C,u} \left| \frac{1}{n} \sum_{i=1}^n I(f_C(X_i) > u) - \mathbb{P}(f_C(Z) > u) \right|$$

$$= 8B \sup_{A} \left| \frac{1}{n} \sum_{i=1}^n I(X_i \in A) - \mathbb{P}(A) \right|$$

where A varies over all sets  $\mathcal{A}$  of the form  $\{f_C(x) > u\}$ . The shattering number of  $\mathcal{A}$  is  $s(\mathcal{A}, n) \leq n^{k(d+1)}$ . This follows since each set  $\{f_C(x) > u\}$  is a union of the complements of k spheres. By the VC Theorem,

$$\mathbb{P}(R(\widehat{C}) - R(C^*) > \epsilon) \leq \mathbb{P}\left(8B \sup_{A} \left| \frac{1}{n} \sum_{i=1}^{n} I(X_i \in A) - \mathbb{P}(A) \right| > \epsilon\right)$$

$$= \mathbb{P}\left(\sup_{A} \left| \frac{1}{n} \sum_{i=1}^{n} I(X_i \in A) - \mathbb{P}(A) \right| > \frac{\epsilon}{8B}\right)$$

$$\leq 4(2n)^{k(d+1)} e^{-n\epsilon^2/(512B^2)}.$$

Now conclude that  $\mathbb{E}(R(\widehat{C}) - R(C^*)) \leq C\sqrt{k(d+1)}\sqrt{\frac{\log n}{n}}$ .

A sharper result, together with a lower bound is the following.

**Theorem 5 (Bartlett, Linder and Lugosi 1997)** Suppose that  $\mathbb{P}(\|X\|^2 \le 1) = 1$  and that  $n \ge k^{4/d}$ ,  $\sqrt{dk^{1-2/d} \log n} \ge 15$ ,  $kd \ge 8$ ,  $n \ge 8d$  and  $n/\log n \ge dk^{1+2/d}$ . Then,

$$\mathbb{E}(R(\widehat{C})) - R(C^*) \le 32\sqrt{\frac{dk^{1-2/d}\log n}{n}} = O\left(\sqrt{\frac{dk\log n}{n}}\right).$$

Also, if  $k \geq 3$ ,  $n \geq 16k/(2\Phi^2(-2))$  then, for any method  $\widehat{C}$  that selects k centers, there exists P such that

$$\mathbb{E}(R(\widehat{C})) - R(C^*) \ge c_0 \sqrt{\frac{k^{1-4/d}}{n}}$$

where  $c_0 = \Phi^4(-2)2^{-12}/\sqrt{6}$  and  $\Phi$  is the standard Gaussian distribution function.

See Bartlett, Linder and Lugosi (1997) for a proof. It follows that (global optimum) k-means is risk consistent in the sense that  $R(\widehat{C}) - R(C^*) \stackrel{P}{\to} 0$ , as long as  $k = o(n/(d \log n))$ . Moreover, the lower bound implies that we cannot find any other method that improves much over the k-means approach, at least with respect to this loss function.

### 3.2 Starting Values for k-means

Since  $\widehat{R}_n(C)$  has multiple minima, Lloyd's algorithm is not guaranteed to minimize  $R_n(C)$ . The clustering one obtains will depend on the starting values. The simplest way to choose starting values is to use k randomly chosen points. But this often leads to poor clustering.

**Example 6** Figure 5 shows data from a distribution with nine clusters. The raw data are in the top left plot. The top right plot shows the results of running the k-means algorithm with k = 9 using random points as starting values. The clustering is quite poor. This is because we have not found the global minimum of the empirical risk function. The two bottom plots show better methods for selecting starting values that we will describe below.

**Hierarchical Starting Values.** Tseng and Wong (2005) suggest the following method for choosing staring values for k-means. Run single-linkage hierarchical clustering (which we describe in Section 6) to obtains  $p \times k$  clusters. They suggest using p = 3 as a default. Now take the centers of the k-largest of the  $p \times k$  clusters and use these as starting values. See the bottom left plot in Figure 5.

k-means<sup>++</sup>. Arthur and Vassilvitskii (2007) invented an algorithm called k-means<sup>++</sup> to get good starting values. They show that if the starting points are chosen in a certain way, then we can get close to the minimum with high probability. In fact the starting points themselves — which we call seed points — are already close to minimizing  $R_n(C)$ . The algorithm is described in Figure 6. See the bottom right plot in Figure 5 for an example.

**Theorem 7** (Arthur and Vassilvitskii, 2007). Let  $C = \{c_1, \ldots, c_k\}$  be the seed points from the k-means<sup>++</sup> algorithm. Then,

$$\mathbb{E}(R_n(C)) \le 8(\log k + 2) \left(\min_C R_n(C)\right) \tag{7}$$

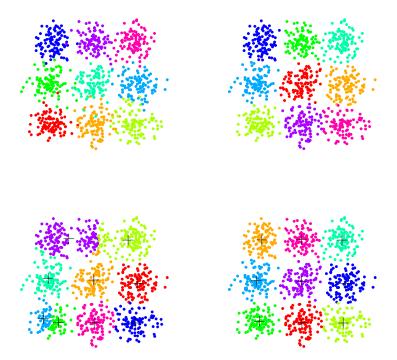

Figure 5: An example with 9 clusters. Top left: data. Top right: k-means with random starting values. Bottom left: k-means using starting values from hierarchical clustering. Bottom right: the k-means<sup>++</sup> algorithm.

- 1. Input: Data  $X = \{X_1, \dots, X_n\}$  and an integer k.
- 2. Choose  $c_1$  randomly from  $X = \{X_1, \ldots, X_n\}$ . Let  $C = \{c_1\}$ .
- 3. For j = 2, ..., k:
  - (a) Compute  $D(X_i) = \min_{c \in C} ||X_i c||$  for each  $X_i$ .
  - (b) Choose a point  $X_i$  from X with probability

$$p_i = \frac{D^2(X_i)}{\sum_{j=1}^n D^2(X_j)}.$$

- (c) Call this randomly chosen point  $c_j$ . Update  $C \longleftarrow C \cup \{c_j\}$ .
- 4. Run Lloyd's algorithm using the **seed points**  $C = \{c_1, \ldots, c_k\}$  as starting points and output the result.

Figure 6: The k-means<sup>++</sup> algorithm.

where the expectation is over the randomness of the algorithm.

See Arthur and Vassilvitskii (2007) for a proof. They also show that the Euclidean distance can be replaced with the  $\ell_p$  norm in the algorithm. The result is the same except that the constant 8 gets replaced by  $2^{p+2}$ . It is possible to improve the k-means<sup>++</sup> algorithm.

### 3.3 Choosing k

In k-means clustering we must choose a value for k. This is still an active area of research and there are no definitive answers. The problem is much different than choosing a tuning parameter in regression or classification because there is no observable label to predict. Indeed, for k-means clustering, both the true risk R and estimated risk  $R_n$  decrease to 0 as k increases. This is in contrast to classification where the true risk gets large for high complexity classifiers even though the empirical risk decreases. Hence, minimizing risk does not make sense. There are so many proposals for choosing tuning parameters in clustering that we cannot possibly consider all of them here. Instead, we highlight a few methods.

#### 3.3.1 Elbow Methods

One approach is to look for sharp drops in estimated risk. Let  $R_k$  denote the minimal risk among all possible clusterings and let  $\widehat{R}_k$  be the empirical risk. It is easy to see that  $R_k$  is a nonincreasing function of k so minimizing  $R_k$  does not make sense. Instead, we can look for the first k such that the improvement  $R_k - R_{k+1}$  is small, sometimes called an elbow. This can be done informally by looking at a plot of  $\widehat{R}_k$ . We can try to make this more formal by fixing a small number  $\alpha > 0$  and defining

$$k_{\alpha} = \min \left\{ k : \frac{R_k - R_{k+1}}{\sigma^2} \le \alpha \right\}$$
 (8)

where  $\sigma^2 = \mathbb{E}(\|X - \mu\|^2)$  and  $\mu = \mathbb{E}(X)$ . An estimate of  $k_{\alpha}$  is

$$\widehat{k}_{\alpha} = \min \left\{ k : \frac{\widehat{R}_k - \widehat{R}_{k+1}}{\widehat{\sigma}^2} \le \alpha \right\}$$
(9)

where 
$$\widehat{\sigma}^2 = n^{-1} \sum_{i=1}^n ||X_i - \overline{X}||^2$$
.

Unfortunately, the elbow method often does not work well in practice because there may not be a well-defined elbow.

#### 3.3.2 Hypothesis Testing

A more formal way to choose k is by way of hypothesis testing. For each k we test

 $H_k$ : the number of clusters is k versus  $H_{k+1}$ : the number of clusters is k.

We begin k = 1. If the test rejects, then we repeat the test for k = 2. We continue until the first k that is not rejected. In summary,  $\hat{k}$  is the first k for which k is not rejected.

A nice approach is the one in Liu, Hayes, Andrew Nobel and Marron (2012). (JASA, 2102, 1281-1293). They simply test if the data are multivariate Normal. If this rejects, they split into two clusters and repeat. The have an R package sigclust for this. A similar procedure, called PG means is described in Feng and Hammerly (2007).

**Example 8** Figure 7 shows a two-dimensional example. The top left plot shows a single cluster. The p-values are shown as a function of k in the top right plot. The first k for which the p-value is larger than  $\alpha = .05$  is k = 1. The bottom left plot shows a dataset with three clusters. The p-values are shown as a function of k in the bottom right plot. The first k for which the p-value is larger than  $\alpha = .05$  is k = 3.

#### 3.3.3 Stability

Another class of methods are based on the idea of stability. The idea is to find the largest number of clusters than can be estimated with low variability.

We start with a high level description of the idea and then we will discuss the details. Suppose that  $Y = (Y_1, \ldots, Y_n)$  and  $Z = (Z_1, \ldots, Z_n)$  are two independent samples from P. Let  $A_k$  be any clustering algorithm that takes the data as input and outputs k clusters. Define the stability

$$\Omega(k) = \mathbb{E}\left[s(A_k(Y), A_k(Z))\right] \tag{10}$$

where  $s(\cdot, \cdot)$  is some measure of the similarity of two clusterings. To estimate  $\Omega$  we use random subsampling. Suppose that the original data are  $X = (X_1, \ldots, X_{2n})$ . Randomly split the data into two equal sets Y and Z of size n. This process if repeated N times. Denote the random split obtained in the  $j^{\text{th}}$  trial by  $Y^j, Z^j$ . Define

$$\widehat{\Omega}(k) = \frac{1}{N} \sum_{j=1}^{N} \left[ s(A_k(Y^j), A_k(Z^j)) \right].$$

For large N,  $\widehat{\Omega}(k)$  will approximate  $\Omega(k)$ . There are two ways to choose k. We can choose a small k with high stability. Alternatively, we can choose k to maximize  $\widehat{\Omega}(k)$  if we somehow standardize  $\widehat{\Omega}(k)$ .

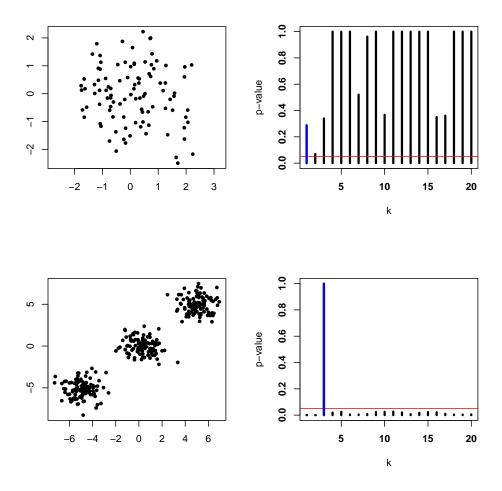

Figure 7: Top left: a single cluster. Top right: p-values for various k. The first k for which the p-value is larger than .05 is k=1. Bottom left: three clusters. Bottom right: p-values for various k. The first k for which the p-value is larger than .05 is k=3.

Now we discuss the details. First, we need to define the similarity between two clusterings. We face two problems. The first is that the cluster labels are arbitrary: the clustering (1,1,1,2,2,2) is the same as the clustering (4,4,4,8,8,8). Second, the clusterings  $A_k(Y)$  and  $A_k(Z)$  refer to different data sets.

The first problem is easily solved. We can insist the labels take values in  $\{1, \ldots, k\}$  and then we can maximize the similarity over all permutations of the labels. Another way to solve the problem is the following. Any clustering method can be regarded as a function  $\psi$  that takes two points x and y and outputs a 0 or a 1. The interpretation is that  $\psi(x,y) = 1$  if x and y are in the same cluster while  $\psi(x,y) = 0$  if x and y are in a different cluster. Using this representation of the clustering renders the particular choice of labels moot. This is the approach we will take.

Let  $\psi_Y$  and  $\psi_Z$  be clusterings derived from Y and Z. Let us think of Y as training data and Z as test data. Now  $\psi_Y$  returns a clustering for Y and  $\psi_Z$  returns a clustering for Z. We'd like to somehow apply  $\psi_Y$  to Z. Then we would have two clusterings for Z which we could then compare. There is no unique way to do this. A simple and fairly general approach is to define

$$\psi_{Y,Z}(Z_j, Z_k) = \psi_Y(Y_i', Y_k') \tag{11}$$

where  $Y'_j$  is the closest point in Y to  $Z_j$  and  $Y'_k$  is the closest point in Y to  $Z_k$ . (More generally, we can use Y and the cluster assignment to Y as input to a classifier; see Lange et al 2004). The notation  $\psi_{Y,Z}$  indicates that  $\psi$  is trained on Y but returns a clustering for Z. Define

$$s(\psi_{Y,Z},\psi_Z) = \frac{1}{\binom{n}{2}} \sum_{s \neq t} I\left(\psi_{Y,Z}(Z_s, Z_t) = \psi_Z(Z_s, Z_t)\right).$$

Thus s is the fraction of pairs of points in Z on which the two clusterings  $\psi_{Y,Z}$  and  $\psi_Z$  agree. Finally, we define

$$\widehat{\Omega}(k) = \frac{1}{N} \sum_{j=1}^{N} s(\psi_{Y^j, Z^j}, \psi_{Z^j}).$$

Now we need to decide how to use  $\widehat{\Omega}(k)$  to choose k. The interpretation of  $\widehat{\Omega}(k)$  requires some care. First, note that  $0 \leq \widehat{\Omega}(k) \leq 1$  and  $\widehat{\Omega}(1) = \widehat{\Omega}(n) = 1$ . So simply maximizing  $\widehat{\Omega}(k)$  does not make sense. One possibility is to look for a small k larger than k > 1 with a high stability. Alternatively, we could try to normalize  $\widehat{\Omega}(k)$ . Lange et al (2004) suggest dividing by the value of  $\widehat{\Omega}(k)$  obtained when cluster labels are assigned randomly. The theoretical justification for this choice is not clear. Tibshirani, Walther, Botstein and Brown (2001) suggest that we should compute the stability separately over each cluster and then take the minimum. However, this can sometimes lead to very low stability for all k > 1.

Many authors have considered schemes of this form, including Breckenridge (1989), Lange, Roth, Braun and Buhmann (2004), Ben-Hur, Elisseeff and Guyron (2002), Dudoit and

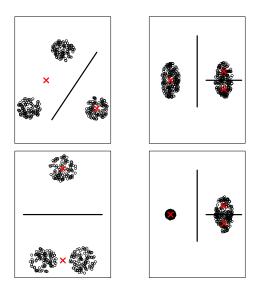

Figure 8: Examples from Ben-David, von Luxburg and Pál (2006). The first example (top left plot) shows a case where we fit k = 2 clusters. Stability analysis will correctly show that k is too small. The top right plot has k = 3. Stability analysis will correctly show that k is too large. The bottom two plots show potential failures of stability analysis. Both cases are stable but k = 2 is too small in the bottom left plot and k = 3 is too big in the bottom right plot.

Fridlyand (2002), Levine and Domany (2001), Buhmann (2010), Tibshirani, Walther, Botstein and Brown (2001) and Rinaldo and Wasserman (2009).

It is important to interpret stability correctly. These methods choose the largest number of stable clusters. That does not mean they choose "the true k." Indeed, Ben-David, von Luxburg and Pál (2006), Ben-David and von Luxburg Tübingen (2008) and Rakhlin (2007) have shown that trying to use stability to choose "the true k" — even if that is well-defined — will not work. To explain this point further, we consider some examples from Ben-David, von Luxburg and Pál (2006). Figure 8 shows the four examples. The first example (top left plot) shows a case where we fit k=2 clusters. Here, stability analysis will correctly show that k is too small. The top right plot has k=3. Stability analysis will correctly show that k is too large. The bottom two plots show potential failures of stability analysis. Both cases are stable but k=2 is too small in the bottom left plot and k=3 is too big in the bottom right plot. Stability is subtle. There is much potential for this approach but more work needs to be done.

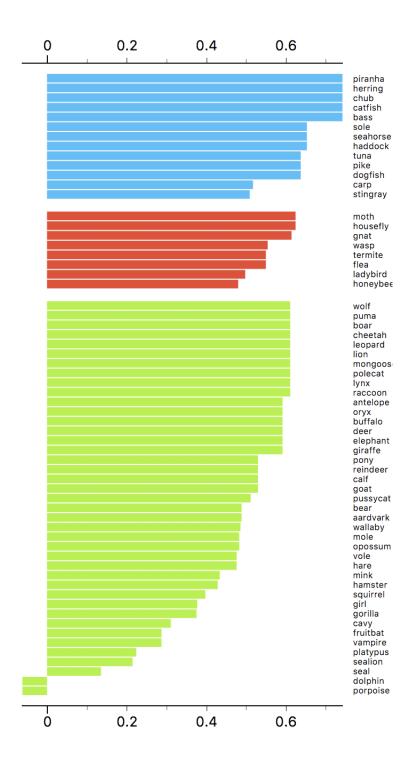

Figure 9: (From Wikipedia) A plot of the silhouette scores of all the data points in each of three clusters. Note that some scores are negative, indicating lack of fit with that cluster.

#### 3.3.4 Silhouette Score

A practically useful approach is based on the silhouette scores, and silhoutte graphs (Rousseeuw 1987).

For each point  $X_i$  in any cluster  $C_i$ , denote its intra-cluster fit as:

$$ic_i = \frac{1}{|C_j| - 1} \sum_{s \in C_j, s \neq i} ||X_i - X_s||,$$

and denote its extra-cluster fit with any of the other clusters as:

$$xc_i = \min_{j' \neq j} \frac{1}{|C_{j'}| - 1} \sum_{s \in C_{j'}} ||X_i - X_s||.$$

We can then define the silhouette value for  $X_i$  as:

$$s_i = \frac{\mathbf{x}\mathbf{c}_i - \mathbf{i}\mathbf{c}_i}{\max\{\mathbf{x}\mathbf{c}_i, \mathbf{i}\mathbf{c}_i\}}, \quad \text{if } |C_j| > 1,$$

where  $C_j$  is the cluster to which  $X_i$  belongs to. Denote  $s_i = 0$  if  $|C_j| = 1$ .

From the definition, it can be seen that  $-1 \le s_i \le 1$ . If  $X_i$  is much much closer to points in its own clusters as compared to the other clusters, then  $s_i$  will be closer to one. On the other hand, when it is closer to points in any other cluster on average compared to points in its own cluster, then  $s_i$  will be negative. The overall silhouette score of the clustering can then be written as:

$$s(\mathcal{C}) = \frac{1}{n} \sum_{i=1}^{n} s_i.$$

But more information can be gleaned by looking at the overall silhoutte graph as in Figure 9. Visual inspection of this silhouette graph might provide more insight into the goodness of a clustering compared to the single numeric silhoutte score, for instance, by indicating if there are many points with poor fit to their clusters.

The k-means algorithm can be generalized in many ways. For example, if we replace the  $L_2$  norm with the  $L_1$  norm we get k-medians clustering. We will not discuss these extensions here.

## 3.4 Overfitting and Merging

The best way to use k-means clustering is to "overfit then merge." Don't think of the k in k-means as the number of clusters. Think of it as a tuning parameter. k-means clustering works much better if we:

- 1. Choose k large
- 2. merge close clusters

This eliminates the sensitivity to the choice of k and it allows k-means to fit clusters with arbitrary shapes. For a theoretical underpinning of this approach, see Aragam, Chen, Xing, Ravikumar, Annals of Statistics, 2019 (more on this in the next section).

### 3.5 k-Means: Population Perspective

If we think about what K-means does at the population or distribution level, it could be viewed as quantization or discretization: obtaining k centroids around each of which there is a lot of probability mass, hopefully tightly concentrated. A density model with a similar perspective is a Gaussian mixture model, where the mixture component means could be viewed as centroids around which the density locally concentrates. Indeed, k-means could be derived as an asymptotic limit (with variance going to zero) of an algorithm to estimate Gaussian mixture models. We will thus study mixture models next.

### 4 Mixture Models

Simple cluster structure can be discovered using mixture models. We start with a simple example. We flip a coin with success probability  $\pi$ . If heads, we draw X from a density  $p_1(x)$ . If tails, we draw X from a density  $p_0(x)$ . Then the density of X is

$$p(x) = \pi p_1(x) + (1 - \pi)p_0(x),$$

which is called a mixture of two densities  $p_1$  and  $p_0$ . Figure 10 shows a mixture of two Gaussians distribution.

Let  $Z \sim \text{Bernoulli}(\pi)$  be the unobserved coin flip. Then we can also write p(x) as

$$p(x) = \sum_{z=0,1} p(x,z) = \sum_{z=0,1} p(x|z)p(z)$$
(12)

where  $p(x|Z=0) := p_0(x)$ ,  $p(x|Z=1) := p_1(x)$  and  $p(z) = \pi^z (1-\pi)^{1-z}$ . Equation (12) is called the hidden variable representation. A more formal definition of finite mixture models is as follows.

[Finite Mixture Models] Let  $\{p_{\theta}(x): \theta \in \Theta\}$  be a parametric class of densities. Define the mixture model

$$p_{\psi}(x) = \sum_{j=0}^{K-1} \pi_j p_{\theta_j}(x),$$

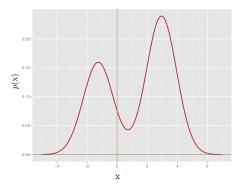

Figure 10: A mixture of two Gaussians,  $p(x) = \frac{2}{5}\phi(x; -1.25, 1) + \frac{3}{5}\phi(x; 2.95, 1)$ .

where the mixing coefficients  $\pi_j \geq 0$ ,  $\sum_{j=0}^{K-1} \pi_j = 1$  and  $\psi = (\pi_0, \dots, \pi_{K-1}, \theta_0, \dots, \theta_{K-1})$  are the unknown parameters. We call  $p_{\theta_0}, \dots, p_{\theta_{K-1}}$  the component densities.

Generally, even if  $\{p_{\theta}(x) : \theta \in \Theta\}$  is an exponential family model, the mixture may no longer be an exponential family.

### 4.1 Mixture of Gaussians

Let  $\phi(x; \mu_j, \sigma_j^2)$  be the probability density function of a univariate Gaussian distribution with mean  $\mu_j$  and variance  $\sigma_j^2$ . A typical finite mixture model is the mixture of Gaussians. In one dimension, we have

$$p_{\psi}(x) = \sum_{j=0}^{K-1} \pi_j \phi(x; \mu_j, \sigma_j^2),$$

which has 3K-1 unknown parameters, due to the restriction  $\sum_{j=0}^{K-1} \pi_j = 1$ .

A mixture of d-dimensional multivariate Gaussians is

$$p(x) = \sum_{j=0}^{K-1} \frac{\pi_j}{(2\pi)^{d/2} |\Sigma_j|^{1/2}} \exp\left\{-\frac{1}{2} (x - u_j)^T \Sigma_j^{-1} (x - u_j)\right\}.$$

There are in total

$$K\bigg(\underbrace{\frac{d(d+1)}{2}}_{\text{\# of parameters in }\Sigma_j} + \underbrace{\frac{d}{\text{\# of parameters in }u_j}}_{\text{\# of parameters in }u_j}\bigg) + \underbrace{(K-1)}_{\text{\# of mixing coefficients}} = \frac{Kd(d+3)}{2} + K - 1$$

parameters in the mixture of K multivariate Gaussians.

#### 4.2 Maximum Likelihood Estimation

A finite mixture model  $p_{\psi}(x)$  has parameters  $\psi = (\pi_0, \dots, \pi_{K-1}, \theta_0, \dots, \theta_{K-1})$ . The likelihood of  $\psi$  based on the observations  $X_1, \dots, X_n$  is

$$\mathcal{L}(\psi) = \prod_{i=1}^{n} p_{\psi}(X_i) = \prod_{i=1}^{n} \left( \sum_{j=0}^{K-1} \pi_j p_{\theta_j}(X_i) \right)$$

and, as usual, the maximum likelihood estimator is the value  $\widehat{\psi}$  that maximizes  $\mathcal{L}(\psi)$ . Usually, the likelihood is multimodal and one seeks a local maximum instead if a global maximum.

For fixed  $\theta_0, \ldots, \theta_{K-1}$ , the log-likelihood is often a concave function of the mixing parameters  $\pi_j$ . However, for fixed  $\pi_0, \ldots, \pi_{K-1}$ , the log-likelihood is not generally concave with respect to  $\theta_0, \ldots, \theta_{K-1}$ .

One way to find  $\widehat{\psi}$  is to apply your favorite optimizer directly to the log-likelihood.

$$\ell(\psi) = \sum_{i=1}^{n} \log \left( \sum_{j=0}^{K-1} \pi_{j} p_{\theta_{j}}(X_{i}) \right).$$

However,  $\ell(\psi)$  is not jointly convex with respect to  $\psi$ . It is not clear which algorithm is the best to optimize such a nonconvex objective function.

A convenient and commonly used algorithm for finding the maximum likelihood estimates of a mixture model (or the more general latent variable models) is the expectation-maximization (EM) algorithm. To discuss this algorithm, we will re-write the statistical model for a mixture of two Gaussians in terms of latent variables as

$$Z \sim \text{Bernouli}(\pi),$$
 (13)

$$X|Z = j \sim N(\mu_j, \Sigma_j) \text{ for } j = 0, 1.$$
(14)

Define

$$p(x|Z=1) := p_{\mu_1,\Sigma_1}(x)$$
 and  $p(x|Z=0) := p_{\mu_0,\Sigma_0}(x)$ .

Let  $X_1, \ldots, X_n$  be the observed data and let  $Z_1, \ldots, Z_n$  be the "missing data". There are two types of unknowns: (i) the parameter vector  $\psi = (\pi, \mu_0, \mu_1)^T$ , and the latent samples  $Z_1, \ldots, Z_n$ . The latent variables  $Z_1, \ldots, Z_n$  can be used for clustering, while  $\psi$  can be used for evaluating the likelihood. The EM algorithm is then similar to a block coordinate ascent procedure, which aims to maximize the log-likelihood function by alternatively inferring the information of  $Z_1, \ldots, Z_n$  (Expectation-step) and estimating the parameter vector  $\psi$  (Maximization-step).

Let us consider the simpler setting where  $\Sigma_0 = \Sigma_1 = I$ .

### The Expectation-Maximization Algorithm for the Mixture of Two Gaussians

Initialize 
$$\psi^{(0)} := (\pi^{(0)}, \mu_1^{(0)}, \mu_0^{(0)})^T$$
.  
For  $t = 1, 2, \dots$  {

• Expectation-Step (E-Step): for i = 1, ..., n, calculate

$$\begin{split} \gamma_i^{(t+1)} &:= \mathbb{P}_{\psi^{(t)}} \left( Z_i = 1 | X_1, \dots, X_n \right) \\ &= \frac{\pi^{(t)} \exp \left[ -\frac{(X_i - \mu_1^{(t)})^2}{2} \right]}{\pi^{(t)} \exp \left[ -\frac{(X_i - \mu_1^{(t)})^2}{2} \right] + (1 - \pi^{(t)}) \exp \left[ -\frac{(X_i - \mu_0^{(t)})^2}{2} \right]}. \end{split}$$

• Maximization-Step (M-Step): Given  $\gamma_i^{(t+1)}$ , we update the parameter  $\psi$  by

$$\pi^{(t+1)} \leftarrow \frac{1}{n} \sum_{i=1}^{n} \gamma_i^{(t+1)};$$

$$\mu_1^{(t+1)} \leftarrow \frac{\sum_{i=1}^{n} \gamma_i^{(t+1)} X_i}{\sum_{i=1}^{n} \gamma_i^{(t+1)}} \text{ and } \mu_0^{(t+1)} \leftarrow \frac{\sum_{i=1}^{n} (1 - \gamma_i^{(t+1)}) X_i}{\sum_{i=1}^{n} (1 - \gamma_i^{(t+1)})}.$$

until convergence.

It can be seen that this is a "softer" version of k-means, where  $\gamma_i$  is a softer cluster assignment of each point to the k centroids, while the corresponding centroids also average the softer cluster assignments.

While the algorithm can be slow to converge, its simplicity, flexibility, and the fact that it doesn't require a choice of step size make it a convenient choice for many estimation problems. Nonetheless, the EM algorithm is only one of many numerical procedures for obtaining a (local) maximum likelihood estimate of the latent variable models. In some cases procedures such as Newton's method or conjugate gradient may be more effective, and should be considered as alternatives to EM.

In principle, there are polynomial time algorithms for finding good estimates of  $\psi$  based on spectral methods and the method of moments. It appears that, at least so far, these methods are not yet practical enough to be used in routine data analysis.

**Example.** The data are measurements on duration and waiting time of eruptions of the Old Faithful geyser from August 1 to August 15, 1985. There are two variables with 299 observations. The first variable, "Duration", represents the numeric eruption time in minutes. The second variable, "waiting", represents the waiting time to next eruption. This data is believed to have two modes. We fit a mixture of two Gaussians using EM algorithm. To illustrate the EM step, we purposely choose a bad starting point. The EM algorithm quickly converges in six steps. Figure 11 illustrates the fitted densities for all the six steps. We see that even though the starting density is unimodal, it quickly becomes bimodal.

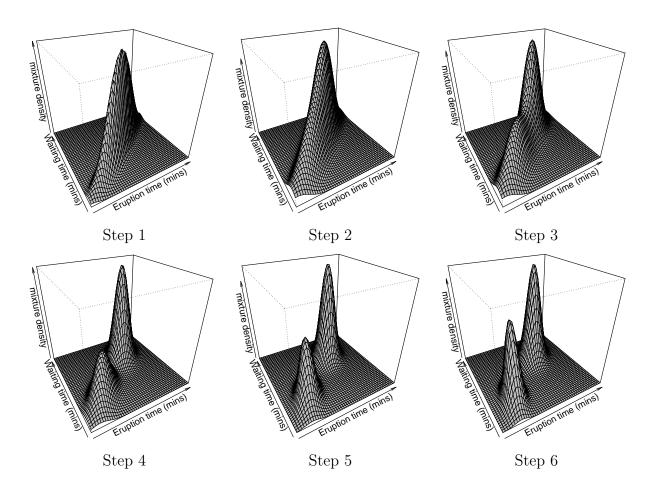

Figure 11: Fitting a mixture of two Gaussians on the Old Faithful Geyser data. The initial values are  $\pi_0 = \pi_1 = 0.5$ .  $u_0 = (4,70)^T$ ,  $u_1 = (3,60)^T$ ,  $\Sigma_1 = \Sigma_2 = \binom{0.8}{7}$ . We see that even though the starting density is not bimodal, the EM algorithm converges quickly to a bimodal density.

## 4.3 Nonparametric Mixture Models

Viewed from an information-theoretic lens, in clustering, we are asking: when can we recover the unseen cluster assignment Y given just the input X? Without much loss of generality, this can be cast as a non-parametric mixture model estimation problem. To see this, suppose we are given some random vector X, and denote the latent clustering assignment variable as Y, that say takes k values. It can then be seen that Y specifies a mixture model:  $P(X) = \sum_{j=1}^{k} P(Y=j) P(X|Y=j)$ , so if we are able to estimate the mixture components, we would be able to recover the clustering corresponding to Y. This is an identifiability question: given the mixture components  $\{P(X|Y)\}$  (and mixture weights) there is obviously a unique input distribution P(X). When is there a unique set of mixture components (and is there a practical recover these) given just P(X)? Obviously, without any information about the

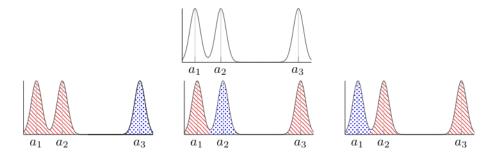

Figure 12: A distribution that is identifiable as a mixture of Gaussians, but not identifiable as a mixture of two sub-Gaussians.

mixture components, the answer is no, since there are many possible mixture models that could have given rise to P(X).

With parametric mixture models, we are given the additional side information that the mixture component distributions lie in a specific parametric family. Classical results on identifiability of mixture models (Yakowitz and Spragins, 1968; Teicher, 1963) state that so long as the specific family of distributions is such that the CDFs of the individual distributions are linearly independent over  $\mathbb{R}$ , the corresponding mixture models are identifiable. This holds true for typical parametric models (e.g. Gaussian mixture models), so that the corresponding mixture model is indeed identifiable: just given P(X), we can in principle recover the mixture components. But the moment we go to non-parametric models, identifiability typicaly fails to hold, even for very simple non-parametric classes.

For instance, consider the mixture of three Gaussians in Figure 12. While we can write the distribution uniquely as a mixture of three Gaussians, we can also write it as three different equally valid representations as a mixture of two sub-Gaussians. Thus, the distribution is not identifiable with respect to a mixture model over sub-Gaussian distributions. Note that even if we assume the number of components are known, and the component means are well-separated, this would still remain non-identifiable: consider two components, and where the third component is arbitrarily far to the right.

(Aragam, Chen, Xing, Ravikumar, Annals of Statistics 2020) provide conditions under which non-parametric mixture models can indeed be identifiable. Loosely: Gaussian mixture models are identifiable, and moreover are dense in the space of all distributions. Thus, each non-parametric mixture component can be approximated well via a mixture of Gaussians, and consequently, the overall distribution as a mixture of Gaussians in turn. Thus, one can project any non-parametric distribution onto a mixture of a large number of Gaussians. Then so long as one could cluster these Gaussian components, then one could identify the individual non-parametric mixture components with each cluster of Gaussian components.

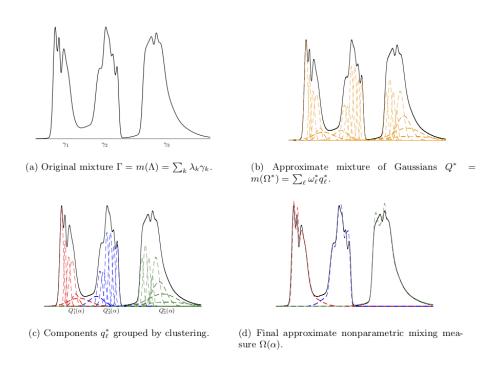

Figure 13: Estimating Non-parametric Mixture Models via Overfitted Gaussian Mixtures

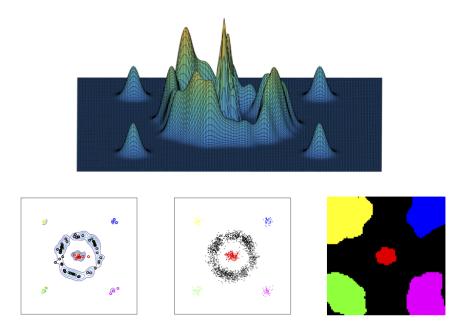

Figure 14: (Top) Density plot of the original mixture density. (Left) Contour plot of overfitted Gaussian mixture approximation, centers marked with small circles. (Middle) Original data color coded by the approximate Bayes optimal partition. (Right) Estimated Bayes optimal partition, visualized by color-coding the input space by estimated cluster membership.

Their paper essentially provided the regularity conditions under which the above very natural procedure is guaranteed to identify the non-parametric mixture components.

The overall algorithm, as shown in Figure 13, then is:

- 1. Estimate an overfitted mixture of Gaussians to the given data
- 2. Cluster the Gaussian densities with respect to say the Hellinger metric
- 3. Identify each cluster with a non-parametric mixture component

Figure 14 provides an example of a difficult clustering example, where the above approach works well.

Given the connection between Gaussian mixture models and K-means, this also suggestive of a theoretical underpinning for the overfitted Kmeans strategy mentioned in the previous section: fit a large number of clusters via K-means, and then merge the (sub)-clusters.

### 4.4 The Twilight Zone

Mixtures models are conceptually simple but they have some strange properties.

Computation. Finding the mle is NP-hard.

Infinite Likelihood. Let  $p_{\psi}(x) = \sum_{j=1}^{k} \pi_{j} \phi(x; \mu_{j}, \sigma_{j}^{2})$ , be a mixture of Gaussians. Let  $\mathcal{L}(\psi) = \prod_{i=1}^{n} p_{\psi}(X_{i})$  be the likelihood function based on a sample of size n. Then  $\sup_{\psi} \mathcal{L}(\psi) = \infty$ . To see this, set  $\mu_{j} = X_{1}$  for some j. Then  $\phi(X_{1}; \mu_{j}, \sigma_{j}^{2}) = (\sqrt{2\pi}\sigma_{j})^{-1}$ . Now let  $\sigma_{j} \to 0$ . We have  $\phi(X_{1}; \mu_{j}, \sigma_{j}^{2}) \to \infty$ . Therefore, the log-likelihood is unbounded. This behavior is very different from a typical parametric model. Fortunately, if we define the maximum likelihood estimate to be a mode of  $\mathcal{L}(\psi)$  in the interior of the parameter space, we get a well-defined estimator.

Multimodality of the Density. Consider the mixture of two Gaussians

$$p(x) = (1 - \pi)\phi(x; \mu_1, \sigma^2) + \pi\phi(x; \mu_0, \sigma^2).$$

You would expect p(x) to be multimodal but this is not necessarily true. The density p(x) is unimodal when  $|\mu_1 - \mu_2| \le 2\sigma$  and bimodal when  $|\mu_1 - \mu_2| > 2\sigma$ . One might expect that the maximum number of modes of a mixture of k Gaussians would be k. However, there are examples where a mixture of k Gaussians has more than k modes. In fact, Edelsbrunner, Fasy and Rote (2012) show that the relationship between the number of modes of p and the number of components in the mixture is very complex.

Nonintinuitive Group Membership. Our motivation for studying mixture modes in this chapter was clustering. But one should be aware that mixtures can exhibit unexpected behavior with respect to clustering. Let

$$p(x) = (1 - \pi)\phi(x; \mu_1, \sigma_1^2) + \pi\phi(x; \mu_2, \sigma_2^2).$$

Suppose that  $\mu_1 < \mu_2$ . We can classify an observation as being from cluster 1 or cluster 2 by computing the probability of being from the first or second component, denoted Z = 0 and Z = 1. We get

$$\mathbb{P}(Z=0|X=x) = \frac{(1-\pi)\phi(x;\mu_1,\sigma_1^2)}{(1-\pi)\phi(x;\mu_1,\sigma_1^2) + \pi\phi(x;\mu_2,\sigma_2^2)}.$$

Define Z(x) = 0 if  $\mathbb{P}(Z = 0|X = x) > 1/2$  and Z(x) = 1 otherwise. When  $\sigma_1$  is much larger than  $\sigma_2$ , Figure 15 shows Z(x). We end up classifying all the observations with large  $X_i$  to the leftmost component. Technically this is correct, yet it seems to be an unintended consequence of the model and does not capture what we mean by a cluster.

Improper Posteriors. Bayesian inference is based on the posterior distribution  $p(\psi|X_1,\ldots,X_n) \propto \mathcal{L}(\psi)\pi(\psi)$ . Here,  $\pi(\psi)$  is the prior distribution that represents our knowledge of  $\psi$  before seeing the data. Often, the prior is improper, meaning that it does not have a finite integral.

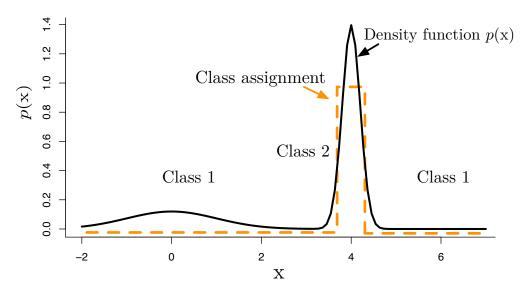

Figure 15: Mixtures are used as a parametric method for finding clusters. Observations with x = 0 and x = 6 are both classified into the first component.

For example, suppose that  $X_1, \ldots, X_n \sim N(\mu, 1)$ . It is common to use an improper prior  $\pi(\mu) = 1$ . This is improper because

$$\int \pi(\mu)d\mu = \infty.$$

Nevertheless, the posterior  $p(\mu|\mathcal{D}_n) \propto \mathcal{L}(\mu)\pi(\mu)$  is a proper distribution, where  $\mathcal{L}(\mu)$  is the data likelihood of  $\mu$ . In fact, the posterior for  $\mu$  is  $N(\overline{X}, 1/\sqrt{n})$  where  $\overline{x}$  is the sample mean. The posterior inferences in this case coincide exactly with the frequentist inferences. In many parametric models, the posterior inferences are well defined even if the prior is improper and usually they approximate the frequentist inferences. Not so with mixtures. Let

$$p(x;\mu) = \frac{1}{2}\phi(x;0,1) + \frac{1}{2}\phi(x;\mu,1). \tag{15}$$

If  $\pi(\mu)$  is improper then so is the posterior. Moreover, Wasserman (2000) shows that the only priors that yield posteriors in close agreement to frequentist methods are data-dependent priors.

**Nonidentifability.** A model  $\{p_{\theta}(x): \theta \in \Theta\}$  is identifiable if

$$\theta_1 \neq \theta_2$$
 implies  $P_{\theta_1} \neq P_{\theta_2}$ 

where  $P_{\theta}$  is the distribution corresponding to the density  $p_{\theta}$ . Mixture models are nonidentifiable in two different ways. First, there is nonidentifiability due to permutation of labels. For example, consider a mixture of two univariate Gaussians,

$$p_{\psi_1}(x) = 0.3\phi(x; 0, 1) + 0.7\phi(x; 2, 1)$$

and

$$p_{\psi_2}(x) = 0.7\phi(x; 2, 1) + 0.3\phi(x; 0, 1),$$

then  $p_{\psi_1}(x) = p_{\psi_2}(x)$  even though  $\psi_1 = (0.3, 0.7, 0, 2, 1)^T \neq (0.7, 0.3, 2, 0, 1)^T = \psi_2$ . This is not a serious problem although it does contribute to the multimodality of the likelihood.

A more serious problem is local nonidentifiability. Suppose that

$$p(x; \pi, \mu_1, \mu_2) = (1 - \pi)\phi(x; \mu_1, 1) + \pi\phi(x; \mu_2, 1). \tag{16}$$

When  $\mu_1 = \mu_2 = \mu$ , we see that  $p(x; \pi, \mu_1, \mu_2) = \phi(x; \mu)$ . The parameter  $\pi$  has disappeared. Similarly, when  $\pi = 1$ , the parameter  $\mu_1$  disappears. This means that there are subspaces of the parameter space where the family is not identifiable. This local nonidentifiability causes many of the usual theoretical properties— such as asymptotic Normality of the maximum likelihood estimator and the limiting  $\chi^2$  behavior of the likelihood ratio test— to break down. For the model (16), there is no simple theory to describe the distribution of the likelihood ratio test for  $H_0: \mu_1 = \mu_2$  versus  $H_1: \mu_1 \neq \mu_2$ . The best available theory is very complicated. However, some progress has been made lately using ideas from algebraic geometry (Yamazaki and Watanabe 2003, Watanabe 2010).

The lack of local identifiability causes other problems too. For example, we usually have that the Fisher information is non-zero and that  $\hat{\theta} - \theta = O_P(n^{-1/2})$  where  $\hat{\theta}$  is the maximum likelihood estimator. Mixture models are, in general, irregular: they do not satisfy the usual regularity conditions that make parametric models so easy to deal with. Here is an example from Chen (1995).

Consider a univariate mixture of two Gaussians distribution:

$$p_{\theta}(x) = \frac{2}{3}\phi(x; -\theta, 1) + \frac{1}{3}\phi(x; 2\theta, 1).$$

Then it is easy to check that I(0) = 0 where  $I(\theta)$  is the Fisher information. Moreover, no estimator of  $\theta$  can converge faster than  $n^{-1/4}$  if the number of components is not known in advance. Compare this to a Normal family  $\phi(x;\theta,1)$  where the Fisher information is  $I(\theta) = n$  and the maximum likelihood estimator converges at rate  $n^{-1/2}$ . Moreover, the distribution of the mle is not even well understood for mixture models. The same applies to the likelihood ratio test.

Mixture Models: Use With Caution. Mixture models can have very unusual and unexpected behavior. This does not mean that we should not use mixture modes. Indeed, mixture models are extremely useful. However, when you use mixture models, it is important to keep in mind that many of the properties of models that we often take for granted, may not hold.

If you are going to use mixture models, it is worthwhile remembering the words of Rod Serling:

There is a fifth dimension beyond that which is known to man. It is a dimension as vast as space and as timeless as infinity. It is the middle ground between light and shadow, between science and superstition, and it lies between the pit of man's fears and the summit of his knowledge. This is the dimension of imagination. It is an area which we call the Twilight Zone.

## 5 Density-Based Clustering

Let p be the density if the data. Let  $L_t = \{x : p_h(x) > t\}$  denote an upper level set of p. Suppose that  $L_t$  can be decomposed into finitely many disjoint sets:  $L_t = C_1 \bigcup \cdots \bigcup C_{k_t}$ . We call  $C_t = \{C_1, \ldots, C_{k_t}\}$  the level set clusters at level t.

Let  $C = \bigcup_{t \geq 0} C_t$ . The clusters in C form a tree: if  $A, B \in C$ , the either (i)  $A \subset B$  or (ii)  $B \subset A$  or (iii)  $A \cap B = \emptyset$ . We call C the level set cluster tree.

The level sets can be estimated in the obvious way:  $\widehat{L}_t = \{x : \widehat{p}_h(x) > t\}$ . How do we decompose  $\widehat{L}_t$  into its connected components? This can be done as follows. For each t let

$$\mathcal{X}_t = \{X_i : \ \widehat{p}_h(X_i) > t\}.$$

Now construct a graph  $G_t$  where each  $X_i \in \mathcal{X}_t$  is a vertex and there is an edge between  $X_i$  and  $X_j$  if and only if  $||X_i - X_j|| \le \epsilon$  where  $\epsilon > 0$  is a tuning parameter. Bobrowski et al (2014) show that we can take  $\epsilon = h$ .  $G_t$  is a called a Rips graphs. The clusters at level t are estimated by taking the connected components of the graph  $G_t$ . In summary:

- 1. Compute  $\widehat{p}_h$ .
- 2. For each t, let  $\mathcal{X}_t = \{X_i : \widehat{p}_h(X_i) > t\}$ .
- 3. Form a graph  $G_t$  for the points in  $\mathcal{X}_t$  by connecting  $X_i$  and  $X_j$  if  $||X_i X_j|| \leq h$ .
- 4. The clusters at level t are the connected components of  $G_t$ .

A Python package, called DeBaCl, written by Brian Kent, can be found at

http://www.brianpkent.com/projects.html.

Fabrizio Lecci has written an R implementation, include in his R package: TDA (topological data analysis). You can get it at:

http://cran.r-project.org/web/packages/TDA/index.html

Two examples are shown in Figures 16 and 17.

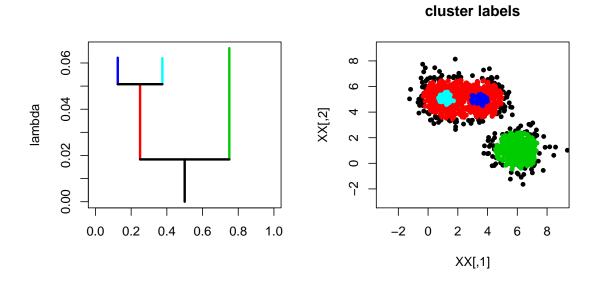

Figure 16: DeBaClR in two dimensions.

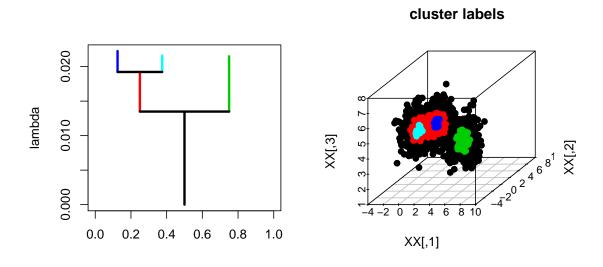

Figure 17: DeBaClR in three dimensions.

### 5.1 Theory

How well does this work? Define the Hausdorff distance between two sets by

$$H(U,V) = \inf \left\{ \epsilon : U \subset V \oplus \epsilon \text{ and } V \subset U \oplus \epsilon \right\}$$

where

$$V \oplus \epsilon = \bigcup_{x \in V} B(x, \epsilon)$$

and  $B(x,\epsilon)$  denotes a ball of radius  $\epsilon$  centered at x. We would like to say that  $L_t$  and  $\widehat{L}_t$  are close. In general this is not true. Sometimes  $L_t$  and  $L_{t+\delta}$  are drastically different even for small  $\delta$ . (Think of the case where a mode has height t.) But we can estimate stable level sets. Let us say that  $L_t$  is stable if there exists a > 0 and C > 0 such that, for all  $\delta < a$ ,

$$H(L_{t-\delta}, L_{t+\delta}) \leq C\delta.$$

**Theorem 9** Suppose that  $L_t$  is stable. Then  $H(\widehat{L}_t, L_t) = O_P(\sqrt{\log n/(nh^d)})$ .

**Proof.** Let  $r_n = \sqrt{\log n/(nh^d)}$ ). We need to show two things: (i) for every  $x \in L_t$  there exists  $y \in \widehat{L}_t$  such that  $||x - y|| = O_P(r_n)$  and (ii) for every  $x \in \widehat{L}_t$  there exists  $y \in L_t$  such that  $||x - y|| = O_P(r_n)$ . First, we note that, by earlier results,  $||\widehat{p}_h - p_h||_{\infty} = O_P(r_n)$ . To show (i), suppose that  $x \in L_t$ . By the stability assumption, there exists  $y \in L_{t+r_n}$  such that  $||x - y|| \le Cr_n$ . Then  $p_h(y) > t + r_n$  which implies that  $\widehat{p}_h(y) > t$  and so  $y \in \widehat{L}_t$ . To show (ii), let  $x \in \widehat{L}_t$  so that  $\widehat{p}_h(x) > t$ . Thus  $p_h(x) > t - r_n$ . By stability, there is a  $y \in L_t$  such that  $||x - y|| \le Cr_n$ .  $\square$ 

#### 5.2 Persistence

Consider a smooth density p with  $M = \sup_x p(x) < \infty$ . The t-level set clusters are the connected components of the set  $L_t = \{x : p(x) \ge t\}$ . Suppose we find the upper level sets  $L_t = \{x : p(x) \ge t\}$  as we vary t from M to 0. Persistent homology measures how the topology of  $L_t$  varies as we decrease t. In our case, we are only interested in the modes, which correspond to the zeroth order homology. (Higher order homology refers to holes, tunnels etc.) The idea of using persistence to study clustering was introduced by Chazal, Guibas, Oudot and Skraba (2013).

Imagine setting t = M and then gradually decreasing t. Whenever we hit a mode, a new level set cluster is born. As we decrease t further, some clusters may merge and we say that one of the clusters (the one born most recently) has died. See Figure 18.

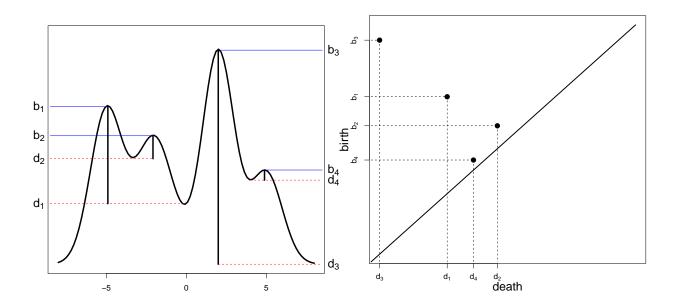

Figure 18: Starting at the top of the density and moving down, each mode has a birth time b and a death time d. The persistence diagram (right) plots the points  $(d_1, b_1), \ldots, (d_4, b_4)$ . Modes with a long lifetime are far from the diagonal.

In summary, each mode  $m_j$  has a death time and a birth time denoted by  $(d_j, b_j)$ . (Note that the birth time is larger than the death time because we start at high density and move to lower density.) The modes can be summarized with a persistence diagram where we plot the points  $(d_1, b_1), \ldots, (d_k, b_k)$  in the plane. See Figure 18. Points near the diagonal correspond to modes with short lifetimes. We might kill modes with lifetimes smaller than the noise level, as captured by the deviation of the density estimate, and the true density. We measure this via the bootstrap quantile  $\epsilon_{\alpha}$  defined by

$$\epsilon_{\alpha} = \inf \left\{ z : \frac{1}{B} \sum_{b=1}^{B} I\left(||\widehat{p}_{h}^{*b} - \widehat{p}_{h}||_{\infty} > z\right) \le \alpha \right\}.$$
 (17)

Here,  $\widehat{p}_h^{*b}$  is the density estimator based on the  $b^{\text{th}}$  bootstrap sample. This corresponds to killing a mode if it is in a  $2\epsilon_{\alpha}$  band around the diagonal. See Fasy, Lecci, Rinaldo, Wasserman, Balakrishnan and Singh (2014). Note that the starting and ending points of the vertical bars on the level set tree are precisely the coordinates of the persistence diagram. (A more precise bootstrap approach was introduced in Chazal, Fasy, Lecci, Michel, Rinaldo and Wasserman (2014).)

## 6 Hierarchical Clustering

Hierarchical clustering methods build a set of nested clusters at different resolutions. As

we will see, this is very closely related to the density based clustering approach discussed previously.

The are two types of hierarchical clustering: agglomerative (bottom-up) and divisive (top-down). With agglomerative clustering we start with some distance or dissimilarity d(x,y) between points. We then extend this distance so that we can compute the distance d(A,B) between to sets of points A and B.

The three most common ways of extending the distance are:

Single Linkage	$d(A,B) = \min_{x \in A, y \in B} d(x,y)$
Average Linkage	$d(A,B) = \frac{1}{N_A N_B} \sum_{x \in A, y \in B} d(x,y)$
	$d(A,B) = \max_{x \in A, y \in B} d(x,y)$

The algorithm is:

- 1. Input: data  $X = \{X_1, \dots, X_n\}$  and metric d giving distance between clusters.
- 2. Let  $T_n = \{C_1, C_2, \dots, C_n\}$  where  $C_i = \{X_i\}$ .
- 3. For j = n 1 to 1:
  - (a) Find j, k to minimize  $d(C_j, C_k)$  over all  $C_j, C_k \in T_{j+1}$ .
  - (b) Let  $T_j$  be the same as  $T_{j+1}$  except that  $C_j$  and  $C_k$  are replaced with  $C_j \cup C_k$ .
- 4. Return the sets of clusters  $T_1, \ldots, T_n$ .

The result can be represented as a tree, called a dendogram. We can then cut the tree at different places to yield any number of clusters ranging from 1 to n. Single linkage often produces thin clusters while complete linkage is better at rounder clusters. Average linkage is in between.

**Example 10** Figure 19 shows agglomerative clustering applied to data generated from two rings plus noise. The noise is large enough so that the smaller ring looks like a blob. The data are show in the top left plot. The top right plot shows hierarchical clustering using single linkage. (The tree is cut to obtain two clusters.) The bottom left plot shows average linkage and the bottom right plot shows complete linkage. Single linkage works well while average and complete linkage do poorly.

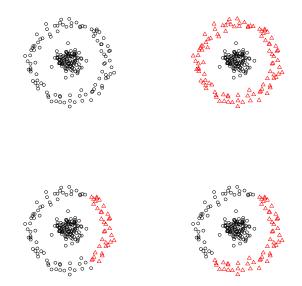

Figure 19: Hierarchical clustering applied to two noisy rings. Top left: the data. Top right: two clusters from hierarchical clustering using single linkage. Bottom left: average linkage. Bottom right: complete linkage.

Finally, let us mention **divisive clustering**. This is a form of hierarchical clustering where we start with one large cluster and then break the cluster recursively into smaller and smaller pieces.

## 6.1 Hierarchical Clustering & Density based Clustering

As we will see in this section, hierarchical clustering and density based clustering are very closely related. Suppose that  $X_1, \ldots, X_n$  is a sample from a distribution P on  $\mathbb{R}^d$  with density p. Recall that in density based clustering, we extract maximal connected components of level sets  $\{x: p(x) \geq \lambda\}$ .

Let us next revisit single linkage hierarchical clustering discussed in the previous section. Let's look at this from the perspective of partitioning a graph. Let G = (V, E) be a graph where  $V = \{X_1, \ldots, X_n\}$  and  $E_{ij} = 1$  if  $||X_i - X_j|| \le \epsilon$  and  $E_{ij} = 0$  if  $||X_i - X_j|| > \epsilon$ . Let  $C_1, \ldots, C_k$  denote the connected components of the graph. We can then see that as we vary  $\epsilon$  we get exactly the hierarchical clustering tree.

But varying  $\epsilon$  and hence the distance of the nearest neighbor can be viewed as extracting a high-density set i.e. a level set of the density. One might thus expect that single linkage clusters would exactly correspond to high density clusters. This turns out not quite to be the case as was pointed out by Hartigan (1981). Loosely, higher up in the hierarchical clustering tree, clusters get large enough that they might intersect with multiple connected components

of the density level sets. So Hartigan (1981) suggested that to obtain high density clusters from single linkage clustering, we need to make it more "robust," and remove points from lower density regions that would not have made the corresponding density level set.

Chaudhuri and DasGupta (2010) formalized this, and suggested the following modified version of hierarchical clustering that attempts to fix this problem, and which can be seen to be very similar to density clustering introduced earlier:

- 1. For each  $x_i$ , let  $r_k(x_i) = \{\inf r : B(x_i, r) \text{ contains } k \text{ data points} \}$ .
- 2. As r increases from 0 to  $\infty$ :
  - (a) Construct a graph  $G_r$  with nodes  $\{x_i: r_k(x_i) \leq r\}$ . Include edge  $(x_i, x_j)$  if  $||x_i x_j|| \leq \alpha r$ .
  - (b) Output  $\widehat{C}(r)$  as the connected components of  $G_r$ .

Here, the neighborhood radius parameter r ranging from 0 to  $\infty$  corresponds to the level set parameter  $\lambda$  in density clustering ranging from 0 to  $\infty$ . In both cases, we remove points corresponding to lower density regions: in this case, by checking if the point has at least k nearest neighbors within that radius. There are two parameters here: k and  $\alpha$ . It can be seen that single linkage is obtained by setting  $\alpha = 1, k = 2$ . More robust versions can be obtained by setting k to be much larger. Chaudhuri and DasGupta (2010) showed that  $\alpha \geq \sqrt{2}$ , and  $k \sim d \log n$  suffices to obtain consistent estimates of high density clusters.

# 7 High-Dimensional Clustering

As usual, interesting and unexpected things happen in high dimensions. The usual methods may break down and even the meaning of a cluster may not be clear.

We will begin by discussing some recent results from Sarkar and Ghosh (arXiv:1612.09121). Suppose we have data coming from k distributions  $P_1, \ldots, P_k$ . Let  $\mu_r$  be the mean of  $P_r$  and  $\Sigma_r$  be the covariance matrix. Most clustering methods depend on the pairwise distances  $||X_i - X_j||^2$ . Now,

$$||X_i - X_j||^2 = \sum_{a=1}^d \delta(a)$$

where  $\delta_a = (X_i(a) - X_j(a))^2$ . This is a sum. As d increases, by the law of large numbers we might expect this sum to converge to a number (assuming the features are not too dependent). Indeed, suppose that X is from  $P_r$  and Y is from  $P_s$  then

$$\frac{1}{\sqrt{d}}||X - Y|| \xrightarrow{P} \sqrt{\sigma_r^2 + \sigma_s^2 + \nu_{rs}}$$

where

$$\nu_{rs} = \lim_{d \to \infty} \frac{1}{d} \sum_{a=1}^{d} ||\mu_r(a) - \mu_s(a)||^2$$

and

$$\sigma_r^2 = \lim_{d \to \infty} \frac{1}{d} \operatorname{trace}(\Sigma_r).$$

Note that  $\nu_{rr} = 0$ .

Consider two clusters,  $C_1$  and  $C_2$ :

If

$$\sigma_1^2 + \nu_{12} < \sigma_2^2$$

then every point in cluster 2 is closer to a point in cluster 1 than to other points in cluster 2. Indeed, if you simulate high dimensional Gaussians, you will see that all the standard clustering methods fail terribly.

What's really going on is that high dimensional data tend to cluster on rings. Pairwise distance methods don't respect rings.

## 8 Modes

Now that we have looked at various approaches to extract a partition of the input space i.e. clusters given P, let's look at approaches to extract other types of low-dimensional structure. A very important such notion is that of modes: which are the local maxima of the density p of the distribution.

Let p be the density of  $X \in \mathbb{R}^d$ . Assume that p has modes  $m_1, \ldots, m_{k_0}$  and that p is a *Morse function*, which means that the Hessian of p at each stationary point is non-degenerate.

## 8.1 Mode Integral Curves

Given any point  $x \in \mathbb{R}^d$ , there is a unique gradient ascent path, or integral curve, passing through x that eventually leads to one of the modes.

Figure 20: A synthetic example with two "blob-like" clusters.

Figure 21: A synthetic example with four clusters with a variety of different shapes.

Formally, an integral curve through x is a path  $\pi_x : \mathbb{R} \to \mathbb{R}^d$  such that  $\pi_x(0) = x$  and

$$\pi_x'(t) = \nabla p(\pi_x(t)). \tag{18}$$

Integral curves never intersect (except at stationary points) and they partition the space.

Equation (18) means that the path  $\pi$  follows the direction of steepest ascent of p through x. The destination of the integral curve  $\pi$  through a (non-mode) point x is defined by

$$\operatorname{dest}(x) = \lim_{t \to \infty} \pi_x(t). \tag{19}$$

It can then be shown that for all x,  $dest(x) = m_j$  for some mode  $m_j$ . That is: all integral curves lead to modes. For each mode  $m_j$ , define the sets

$$\mathcal{A}_j = \left\{ x : \operatorname{dest}(x) = m_j \right\}. \tag{20}$$

These sets are known as the ascending manifolds, or the basin of attraction of  $m_j$ . The  $\mathcal{A}_j$ 's partition the space. See Figure 22. The collection of ascending manifolds is called the Morse complex.

Given data  $X_1, \ldots, X_n$  we construct an estimate  $\widehat{p}$  of the density. Let  $\widehat{m}_1, \ldots, \widehat{m}_k$  be the estimated modes and let  $\widehat{\mathcal{A}}_1, \ldots, \widehat{\mathcal{A}}_k$  be the corresponding ascending manifolds derived from  $\widehat{p}$ . The sample clusters  $C_1, \ldots, C_k$  are defined to be  $C_j = \{X_i : X_i \in \widehat{\mathcal{A}}_j\}$ .

Recall that the kernel density estimator is

$$\widehat{p}(x) \equiv \widehat{p}_h(x) = \frac{1}{n} \sum_{i=1}^n \frac{1}{h^d} K\left(\frac{||x - X_i||}{h}\right)$$
(21)

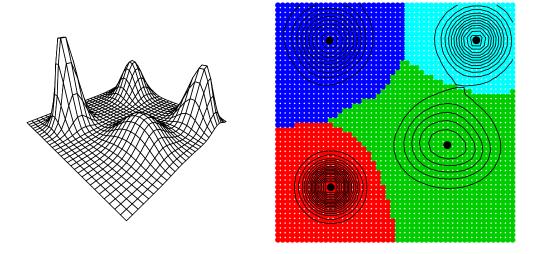

Figure 22: The left plot shows a function with four modes. The right plot shows the ascending manifolds (basins of attraction) corresponding to the four modes.

where K is a smooth, symmetric kernel and h > 0 is the bandwidth.<sup>1</sup> The mean of the estimator is

$$p_h(x) = \mathbb{E}[\widehat{p}_h(x)] = \int K(t)p(x+th)dt. \tag{22}$$

To locate the modes of  $\widehat{p}_h$  we use the *mean shift algorithm* which finds modes by approximating the steepest ascent paths. The algorithm is given in Figure 23, and is essentially a fixed point iteration obtained by setting the gradient of the kernel estimate to zero. Consider the RBF Kernel density estimate:

$$\widehat{p}_h(x) = \frac{1}{nh^d} \sum_{i=1}^n \exp\left(-\frac{\|x - X_i\|^2}{2h^2}\right).$$

Then, its gradient is given as:

$$\nabla_x \widehat{p}_h(x) = \frac{1}{nh^d} \sum_{i=1}^n \left( \frac{x - X_i}{h^2} \right) \exp\left( -\frac{\|a - X_i\|^2}{2h^2} \right).$$

Setting this to zero can be seen to yield the fixed point iteration in the algorithm.

The result of this process is the set of estimated modes  $\widehat{\mathcal{M}} = \{\widehat{m}_1, \dots, \widehat{m}_k\}.$ 

A modified version of the algorithm is the blurred mean-shift algorithm (Carreira-Perpinan, 2006). Here, we use the data as the mesh and we replace the data with the mean-shifted data at each step. This converges very quickly but must be stopped before everything converges to a single point; see Figures 25 and 26.

In general, we can use a bandwidth matrix H in the estimator, with  $\widehat{p}(x) \equiv \widehat{p}_H(x) = \frac{1}{n} \sum_{i=1}^n K_H(x - X_i)$  where  $K_H(x) = |H|^{-\frac{1}{2}} K(H^{-\frac{1}{2}}x)$ .

#### Mean Shift Algorithm

- 1. Input:  $\widehat{p}(x)$  and a mesh of points  $A = \{a_1, \ldots, a_N\}$  (often taken to be the data points).
- 2. For each mesh point  $a_j$ , set  $a_j^{(0)} = a_j$  and iterate the following equation until convergence:

$$a_j^{(s+1)} \longleftarrow \frac{\sum_{i=1}^n X_i K\left(\frac{||a_j^{(s)} - X_i||}{h}\right)}{\sum_{i=1}^n K\left(\frac{||a_j^{(s)} - X_i||}{h}\right)}.$$

- 3. Let  $\widehat{\mathcal{M}}$  be the unique values of the set  $\{a_1^{(\infty)}, \ldots, a_N^{(\infty)}\}$ .
- 4. Output:  $\widehat{\mathcal{M}}$ .

Figure 23: The Mean Shift Algorithm.

#### 8.2 Mode Clustering

We can also obtain a clustering i.e. a partition of the input space using modes, an approach which is also known as mode clustering. We simply define the clusters to be the "basins of attraction" of the modes, the equivalence classes of points whose ascent paths lead to the same mode.

We also get the clustering for free from the mean shift algorithm, which not only estimates the modes but also shows us what mode each point is attracted to. See Figure 24.

What we are doing is tracing out the *gradient flow*. The flow lines lead to the modes and they define the clusters. In general, a flow is a map  $\phi : \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^d$  such that  $\phi(x,0) = x$  and  $\phi(\phi(x,t),s) = \phi(x,s+t)$ . The latter is called the semi-group property.

### 8.3 Choosing the Bandwidth

As usual, choosing a good bandwidth is crucial. You might wonder if increasing the bandwidth, decreases the number of modes. Silverman (1981) showed that the answer is yes if you use a Normal kernel.

**Theorem 11 (Silverman 1981)** Let  $\widehat{p}_h$  be a kernel density estimator using a Gaussian kernel in one dimension. Then the number of modes of  $\widehat{p}_h$  is a non-increasing function of h. The Gaussian kernel is the unique kernel with this property.

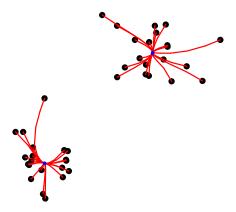

Figure 24: A simple example of the mean shift algorithm.

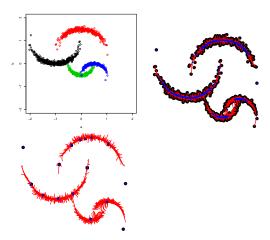

Figure 25: The crescent data example. Top left: data. Top right: a few steps of mean-shift. Bottom left: a few steps of blurred mean-shift.

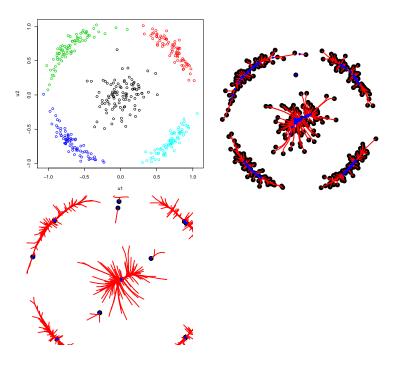

Figure 26: The Broken Ring example. Top left: data. Top right: a few steps of mean-shift. Bottom left: a few steps of blurred mean-shift.

We still need a way to pick h. We can use cross-validation as before. One could argue that we should choose h so that we estimate the gradient  $g(x) = \nabla p(x)$  well since the clustering is based on the gradient flow.

How can we estimate the loss of the gradient? Consider, first the scalar case. Note that

$$\int (\widehat{p}' - p')^2 = \int (\widehat{p}')^2 - 2 \int \widehat{p}p' + \int (p')^2.$$

We can ignore the last term. The first term is known. To estimate the middle term, we use integration by parts to get

$$\int \widehat{p}p' = -\int \widehat{p}''p$$

suggesting the cross-validation estimator

$$\int (\widehat{p}'(x))^2 dx + \frac{2}{n} \sum_{i} \widehat{p}_i''(X_i)$$

where  $\hat{p}_i''$  is the leave-one-out second derivative. More generally, by repeated integration by parts, we can estimate the loss for the  $r^{\text{th}}$  derivative by

$$CV_r(h) = \int (\widehat{p}^{(r)}(x))^2 dx - \frac{2}{n} (-1)^r \sum_i \widehat{p}_i^{(2r)}(X_i).$$

#### 8.4 Theoretical Analysis

How well can we estimate the modes?

**Theorem 12** Assume that p is Morse with finitely many modes  $m_1, \ldots, m_k$ . Then for h > 0 and not too large,  $p_h$  is Morse with modes  $m_{h1}, \ldots, m_{hk}$  and (possibly after relabelling),

$$\max_{j} ||m_{j} - m_{jh}|| = O(h^{2}).$$

With probability tending to 1,  $\widehat{p}_h$  has the same number of modes which we denote by  $\widehat{m}_{h1}, \ldots, \widehat{m}_{hk}$ . Furthermore,

$$\max_{j} ||\widehat{m}_{jh} - m_{jh}|| = O_P \left( \sqrt{\frac{1}{nh^{d+2}}} \right)$$

and

$$\max_{j} ||\widehat{m}_{jh} - m_{j}|| = O(h^{2}) + O_{P}\left(\sqrt{\frac{1}{nh^{d+2}}}\right).$$

**Remark:** Setting  $h \approx n^{-1/(d+6)}$  gives the rate  $n^{-2/(d+6)}$  which is minimax (Tsyabkov 1990) under smoothness assumptions. See also Romano (1988). However, if we take the fixed h point if view, then we have a  $n^{-1/2}$  rate.

**Proof Outline.** But a small ball  $B_j$  around each  $m_{jh}$ . We will skip the first step, which is to show that there is one (and only one) local mode in  $B_j$ . Let's focus on showing

$$\max_{j} ||\widehat{m}_{jh} - m_{jh}|| = O_P \left( \sqrt{\frac{1}{nh^{d+2}}} \right).$$

For simplicity, write  $m = m_{jh}$  and  $x = \widehat{m}_{jh}$ . Let g(x) and H(x) be the gradient and Hessian of  $p_h(x)$  and let  $\widehat{g}(x)$  and  $\widehat{H}(x)$  be the gradient Hessian of  $\widehat{p}_h(x)$ . Then

$$(0, \dots, 0)^T = \widehat{g}(x) = \widehat{g}(m) + (x - m)^T \int_0^1 \widehat{H}(m + u(x - m)) du$$

and so

$$(x-m)^T \int_0^1 \widehat{H}(m+u(x-m))du = (g(m)-\widehat{g}(m))$$

where we used the fact that  $\mathbf{0} = g(m)$ . Multiplying on the right by x - m we have

$$(x-m)^T \int_0^1 \widehat{H}(m+u(x-m))(x-m)du = (\widehat{g}(m)-\widehat{g}(m))^T(x-m).$$

Let  $\lambda = \inf_{0 \le u \le 1} \lambda_{\min}(H(m + u(x - m)))$ . Then  $\lambda = \lambda_{\min}(H(m)) + o_P(1)$  and

$$(x-m)^T \int_0^1 \widehat{H}(x+u(m-x))(x-m)du \ge \lambda ||x-m||^2.$$

Hence, using Cauchy-Schwartz,

$$\lambda ||x-m||^2 \le ||\widehat{g}(m) - g(m)|| \, ||x-m|| \le ||x-m|| \sup_{y} ||\widehat{g}(y) - \widehat{g}(y)|| \le ||x-m|| O_P\left(\sqrt{\frac{1}{nh^{d+2}}}\right)$$

and so 
$$||x - m|| = O_P\left(\sqrt{\frac{1}{nh^{d+2}}}\right)$$
.  $\square$ 

**Remark:** If we treat h as fixed (not decreasing) then the rate is  $O_P(\sqrt{1/n})$  independent of dimension.

### 9 Ridges

A ridge is a high-density, low dimensional structure. A 0-dimensional ridge is just a mode. In this case

$$\nabla p(x) = 0$$
 and  $\lambda_{\max}(H(x)) < 0$ 

where H is the Hessian. (assuming p is Morse). Recall that a mode can also be thought of as the destination of a gradient ascent path,  $\pi_x$ : i.e.

$$m = \lim_{t \to \infty} \pi_x(t)$$

where

$$\pi'_x(t) = \nabla p(\pi_x(t)).$$

The modes of p can be found by the mean-shift algorithm as in Figure 27.

Higher dimensional ridges can be defined as the zeros of a projected gradient. Think of the ridge of a mountain. The left plot in Figure 28 shows a density with a sharp, one-dimensional ridge. The right plot show the underlying manifold, the ridge, and the ridge of the smoothed density.

To define the ridge formally, let p be a density with gradient g and Hessian H. Denote the eigenvalues of H(x) by

$$\lambda_1(x) \ge \lambda_2(x) \ge \dots \ge \lambda_d(x) \ge \lambda_{d+1}(x) \ge \dots \ge \lambda_D(x).$$

Let U(x) = [W(x) : V(x)] be the matrix of eigenvectors. Then  $L(x) = V(x)V^{T}(x)$  is the projector onto the local tangent space. Define the projected gradient G(x) = L(x)g(x).

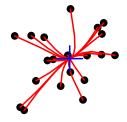

Figure 27: The mean shift algorithm.

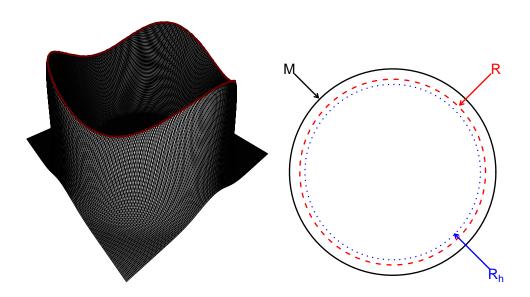

Figure 28: Left: The one-dimensional ridge of a density. Right: the manifold, the ridge of the density p, and the ridge of the smoothed density  $p \star K_h$ .

Finally. define the ridge by

$$R(p) = \left\{ x : \lambda_{d+1}(x) < 0 \text{ and } G(x) = 0 \right\}.$$

Several other definitions of a ridge have been proposed in the literature; see Eberly (1996). The one we use has several useful properties: if  $\hat{p}$  is close to p then  $R(\hat{p})$  is close in Hausdorff distance to R(p).

And, there is an algorithm to find the ridge: the subspace-constrained mean-shift algorithm (SCMS, Ozertem and Erdogmus 2011). (The usual mean-shift algorithm with a projection step.)

To estimate R(p), estimate the density, its gradient, and its Hessian:

$$\widehat{p}(y) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h^{D}} K\left(\frac{y - Y_{i}}{h}\right)$$

 $\widehat{g} = \text{gradient of } \widehat{p} \text{ and } \widehat{H} = \text{Hessian of } \widehat{p}.$  Denoising: remove low density points. Apply the SCMS algorithm.

 $\widehat{R}$  is a consistent estimator of R and:

$$H(R,\widehat{R}) = O_P\left(n^{-\frac{2}{8+D}}\right)$$

For fixed bandwidth h (which still captures the shape),

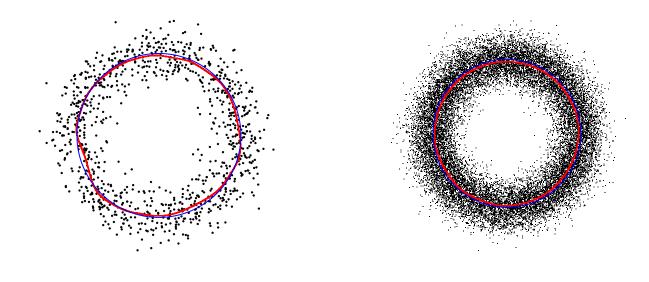

$$H(R_h, \widehat{R}_h) = O_P\left(\sqrt{\frac{\log n}{n}}\right)$$

and  $\widehat{R}_h$  is (nearly) homotopic to  $R_h$ . See Figures 29 and 30 for examples. A real example is shown in 31 (from Chen, Ho, Freeman, Genovese and Wasserman: arXiv:1501.05303).

How to choose a good bandwidth h is not clear. Figure 32 shows that the ridge is fairly stable as we decrease h until we reach a phase transition where the ridge falls apart.

### 10 Manifolds

A common assumption is that P is supported on a (low-dimensional) manifold M. This is usually a bogus assumption. More realistically, the data might be concentrated near a low dimensional structure. Assuming that the structure is smooth and that the support is exactly on this structure is unrealistic. But it is a starting place.

 $\label{eq:control_equation} \mbox{Figure 29: $Left: Manifold in blue. Estimated ridge in red. Right: sample example with more $data.}$ 

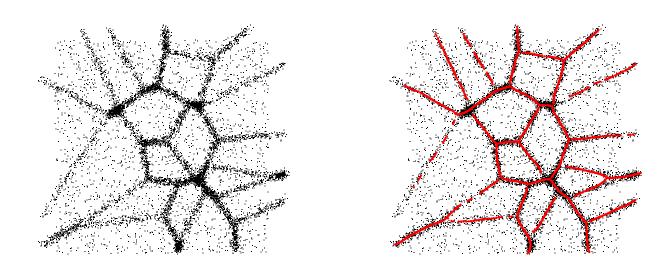

Figure 30: Left: data. Right: SCMS output.

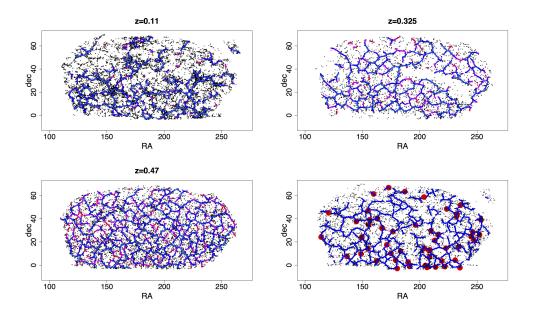

Figure 31: Galaxy data from the Sloan Digital Sky Survey at three different redshifts. The fourth plot shows known galaxy clusters. From: Chen, Ho, Freeman, Genovese and Wasserman: arXiv:1501.05303

So, for now, assume that  $Y_i \in \mathbb{R}^D$  and that P is supported on a manifold M of dimension d < D, and that our goal is to estimate this manifold M.

Just as we needed some conditions on a density function or regression function to estimate it, we needed a condition on a manifold to estimate it. The most common condition is that M has positive reach. The reach of a manifold M is the largest r such that  $d(x, M) \leq r$  implies that x has a unique projection onto M. This is also called the thickness or condition number of the manifold; see Niyoki, Smale, and Weinberger (2009). Intuitively, a manifold M with reach(M) =  $\kappa$  has two constraints:

- 1. Curvature. A ball or radius  $r \leq \kappa$  can roll freely and smoothly over M, but a ball or radius  $r > \kappa$  cannot.
- 2. Separation. M is at least  $2\kappa$  from self-intersecting.

See Figure 33. Also, normal vectors of length less than  $\kappa$  will not cross. See Figure 34.

The easiest way to estimate a d-manifold embedded in  $\mathbb{R}^D$  is just to estimate the support of P. For example, the Devroye-Wise (1980) estimator is

$$\widehat{M} = \bigcup_{i} B(Y_i, \epsilon).$$

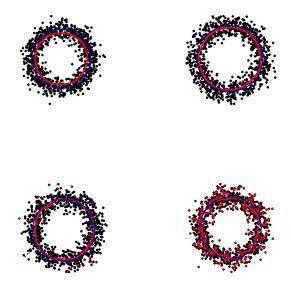

Figure 32: As we decrease the bandwidth, the ridge is quite stable. Eventually we reach a phase transition where the estimated ridge falls apart.

We define the minimax risk

$$R_n = \inf_{\widehat{M}} \sup_{P \in \mathcal{P}} \mathbb{E}_P[H(\widehat{M}, M(P))]$$

where H is the Hausdorff distance:

$$H(A, B) = \inf\{\epsilon : A \subset B \oplus \epsilon \text{ and } B \subset A \oplus \epsilon\}$$

and

$$A \oplus \epsilon = \bigcup_{x \in A} B(x, \epsilon).$$

Choosing  $\epsilon_n \simeq (1/n)^{1/D}$  we get

$$\mathbb{E}[H(\widehat{M}, M)] \le \left(\frac{C \log n}{n}\right)^{\frac{1}{D}}.$$

This estimator is simple but sub-optimal. Note that the rate depends on the ambient dimension.

Let  $Y_1, \ldots, Y_n \sim P$  where

$$Y_i = \xi_i + Z_i$$

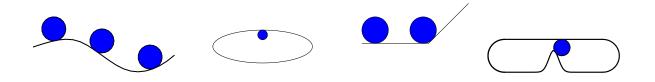

Figure 33: First two plots: a ball of raidus  $r < \kappa$  rolls freely. Third plot: ball cannot roll because reach is 0. Fourth: ball cannot roll because  $r > \kappa$ .

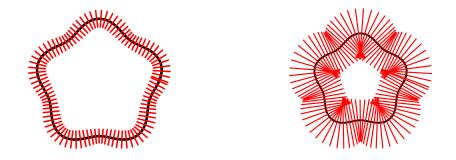

Figure 34: Left: Normal vectors of length  $r < \kappa$  don't cross. Right: Normal vectors of length  $r > \kappa$  do cross.

where  $Y_i \in \mathbb{R}^D$ ,  $\xi_1, \ldots, \xi_n \sim G$  where G is uniform on a d-manifold M and the noise  $Z_i$  is perpendicular to M (uniform on the normals). It's a weird model but it was used in Niyogi, Smale, Weinberger (2008). Let  $\mathcal{P}$  be the set of distributions with bounded density on d-manifolds with reach at least  $\kappa$ . Then (GPVW 2011)

$$R_n = c \left(\frac{\log n}{n}\right)^{\frac{2}{2+d}}.$$

Thus the rate depends on d not D. I don't know a practical estimator to achieve this rate.

Now suppose that

$$Y_1,\ldots,Y_n\sim (1-\pi)U+\pi G$$

where G is supported on M,  $0 < \pi \le 1$ , U is uniform on a compact set  $\mathcal{K} \subset \mathbb{R}^D$ . Then (GPVW 2012)

$$R_n \simeq \left(\frac{1}{n}\right)^{\frac{2}{d}}.$$

A more realistic model is  $Y_i = X_i + Z_i$  where  $X_1, \ldots, X_n \sim G$  and and  $Z_i \sim N(0, \sigma^2 I_D)$ . Then

$$\frac{1}{\log n} \le R_n \le \frac{1}{\sqrt{\log n}}.$$

This means that, with additive noise, the problem is hopeless.

# 11 Dimension of Manifold

In some applications, what we might care about is simply the dimensionality of the lower-dimensional manifold rather than the manifold itself. Say we are given points  $\{x_i\}_{i=1}^n \subseteq \mathbb{R}^D$  drawn from some distribution P.

For the *i*-th data point  $x_i$ , define

$$C_i(\epsilon) = \{x_j \ j \in [n], j \neq i \ | \ ||x_i - x_j|| < \epsilon \}.$$

At reasonable radius  $\epsilon$ , we can expect  $C_i(\epsilon)$  to scale as  $\epsilon^d$  where d is the intrinsic dimension. See Figure 11 for too small or large values of  $\epsilon$ : the resulting manifold itself might look different.

(Grassberger and Procaccia) define the more stable estimate:

$$C(\epsilon) = \sum_{i=1}^{n} C_i(\epsilon),$$

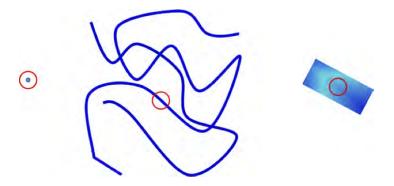

Figure 35: (from Burges 2010) Circle of reducing radius from left to right. At the "right" radius, the number of neighbors scales as radius to the power of manifold dimension.

or even:

$$C(\epsilon) = \frac{1}{n(n-1)} |\{i, j \in [n], i \neq j \mid ||x_i - x_j|| < \epsilon\}|.$$

We can then plot  $\log C(\epsilon)$  against  $\log \epsilon$  and measure the slope to get an estimate of the intrinsic dimension; see Figure 36.

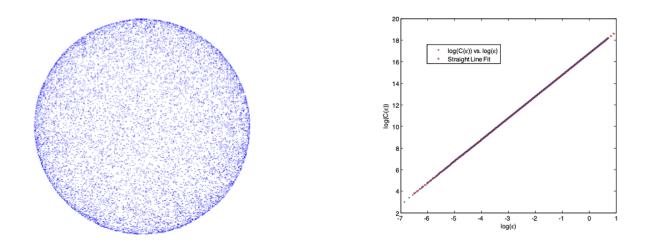

Figure 36: Left: Samples uniformly distributed across 2-sphere. Right: Straight-line fit for the samples from the left.

This works well when the ambient dimension D is small, but might fail to do so for high D; indeed, it is known to underestimate the intrinsic dimension in such cases. As we saw earlier with clustering as well, high-dimensional vectors are near orthogonal, and so normalized vectors will have small inner product and be near equi-distant. We can thus not expect a purely distance based approach as above to do well.

## 12 Summary

We looked at various notions of low-dimensional structure of a distribution P, most of which are very difficult to estimate in the non-parametric regime where P does not belong to a finite-dimensional parametric family. One solution is to give up on estimating M and instead estimate features that "respect" M. This is the next topic of representation learning.
