LAYOUTS FOR THE SHUFFLE-EXCHANGE GRAPH BASED ON THE COMPLEX PLANE DIAGRAM*

FRANK THOMSON LEIGHTON,† MARGARET LEPLEY† AND GARY L. MILLER†

Abstract. The shuffle-exchange graph is one of the best structures known for parallel computation. Among the things, a shuffle-exchange computer can be used to compute discrete Fourier transforms, multiply matrices, evaluate polynomials, perform permutations and sort lists. The algorithms needed for these operations are quite simple and many require no more than logarithmic time and space per processor. In this paper, we analyze the algebraic structure of the shuffle-exchange graph in order to find area-efficient embeddings of the graph in a two-dimensional grid. The results are applicable to the design of Very Large Scale Integration (VLSI) circuit layouts for a shuffle-exchange computer.

Key words. area-efficient chip layouts, complex plane diagram, graph embedding, necklace, shuffle-exchange graph, Thompson grid model, Very Large Scale Integration (VLSI)

1. Introduction. The shuffle-exchange graph has long been recognized as one of the best structures known for parallel computation. Among its many applications, a shuffle-exchange computer can be used to compute discrete Fourier transforms, multiply matrices, evaluate polynomials, perform permutations and sort lists [S71], [P80], [S80]. The algorithms needed for these operations are quite simple and many require no more than logarithmic time and space per processor.

Recent developments in Very Large Scale Integration (VLSI) circuit technology have made it possible to fabricate large numbers of very simple processors on a single chip. As most of the processors contained in a shuffle-exchange computer are very simple, the shuffle-exchange graph serves as an excellent basis upon which to design and build chip-sized microcomputers. One of the main difficulties with such an architecture, however, is the problem of routing the wires which link the processors together in a shuffle-exchange network. Current fabrication technology limits the designer to two or three layers of insulated wiring on a chip and demands that he make the chip as small in area as possible.

Abstracted, the designer's problem becomes the mathematical question of how to embed the shuffle-exchange graph in the smallest possible two-dimensional grid. Thompson was the first to formalize the question mathematically. In his thesis [T80], he showed that any *layout* (i.e., embedding in a two-dimensional grid) of the N-node shuffle-exchange graph requires at least $\Omega(N^2/\log^2 N)$ area. In addition, he described a layout requiring only $O(N^2/\log^{1/2} N)$ area. Shortly thereafter, Hoey and Leiserson [HL80] described an embedding for the shuffle-exchange graph in the complex plane (which we call the *complex plane diagram*) and showed how the diagram could be used to find an $O(N^2/\log N)$-area layout for the N-node shuffle-exchange graph.

In this paper, we investigate the algebraic properties of the complex plane diagram in order to find several $O(N^2/\log^{3/2} N)$-area layouts for the N-node shuffle-exchange graph. In addition to being *asymptotically* superior to previously discovered layouts, the layouts described in this paper are also superior for *small* values of N. In fact, one of these layouts serves as the basis for the more recent work of Leighton and

† Mathematics Department and Laboratory for Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

Miller who have described *optimal* layouts for *small* shuffle-exchange graphs in [LM81].

Subsequent to the completion of the research presented in this paper, we learned that Rodeh and Steinberg independently discovered an $O(N^2/\log^{3/2} N)$-area layout for the N-node shuffle-exchange graph. Their work is also based on the complex plane diagram and appears in [SR81]. Even more recently, Kleitman, Leighton, Lepley and Miller [KLLM81] have discovered an entirely new method for laying out shuffle-exchange graphs which can be used to find *asymptotically optimal* $O(N^2/\log^2 N)$-area layouts. Although their layouts are not entirely practical, they are the only layouts known to achieve Thompson's lower bound asymptotically.

The remainder of the paper is divided into six sections. In § 2, we define the shuffle-exchange graph and the grid model of a chip. We also describe Thompson's $O(N^2/\log^{1/2} N)$-area layout for the N-node shuffle-exchange graph. In § 3, we define the complex plane diagram for the shuffle-exchange graph and mention several of its properties. In § 4, we describe several layouts for the shuffle-exchange graph which are based on the complex plane diagram. These include a straightforward $O(N^2/\log N)$-area layout and several new $O(N^2/\log^{3/2} N)$-area layouts. Section 5 contains some remarks and open questions, and §§ 6 and 7 contain the acknowledgments and references.

2. Preliminaries.

2a. The shuffle-exchange graph. The *shuffle-exchange graph* comes in various sizes. In particular, there is an N-node shuffle-exchange graph for every N which is a power of two. Each node of the $(N = 2^k)$-node shuffle-exchange graph is associated with a unique k-bit binary string $a_{k-1} \cdots a_0$. Two nodes w *and* w' are linked via a *shuffle edge* if w' is a left or right cyclic 1-shift of w (i.e., if $w = a_{k-1} \cdots a_0$ and $w' = a_{k-2} \cdots a_0 a_{k-1}$ or $w' = a_0 a_{k-1} \cdots a_1$, respectively). Two nodes w and w' are linked via an *exchange edge* if w and w' differ only in the last bit (i.e., if $w = a_{k-1} \cdots a_1 0$ and $w' = a_{k-1} \cdots a_1 1$ or vice versa). As an example, we have drawn the 8-node shuffle-exchange graph in Fig. 1. Note that the shuffle edges are drawn with solid lines while the exchange edges are drawn with dashed lines. We shall follow this convention throughout the paper.

FIG. 1. *The 8-node shuffle-exchange graph.*

By replacing the nodes and edges of the shuffle-exchange graph by processors and wires (respectively), the shuffle-exchange graph can be transformed into a very powerful parallel computer (which we call the *shuffle-exchange computer*). The computational power of the shuffle-exchange computer is partly derived from the fact that every pair of nodes in an N-node shuffle-exchange graph is linked by a path containing at most $2 \log N$ edges and thus the communication time between any pair of processors is short.

More importantly, however, the shuffle-exchange computer is capable of performing a perfect shuffle on a set of data in a single parallel operation. For example, consider a deck of 8 cards distributed among the 8 processors of the 8-node shuffle-exchange graph so that processor 000 initially has card 0, processor 001 initially has card 1, processor 010 initially has card 2, and so forth. Next, consider a (parallel) operation of the shuffle-exchange computer in which each processor $a_2a_1a_0$ sends its card across a shuffle edge to the neighboring processor $a_1a_0a_2$. It is easily verified that, after completion of the operation, processor 000 contains card 0 (the top card in the shuffled deck), processor 001 contains card 4 (the second card in the shuffled deck), and so forth.

The power of card shuffling and its mathematical abstractions is well known to magicians and mathematicians [DGK81] as well as to computer scientists [S71, S80]. For a good survey of the computational power of the shuffle-exchange graph, we recommend Schwartz' paper on ultracomputers [S80]. In addition, Stone's paper [S71] contains a nice description of some important parallel algorithms based on the shuffle-exchange graph.

2b. The grid model. Among the many mathematical models that have been proposed for VLSI computation, the most widely accepted is due to Thompson and is known as the *Thompson grid model* [T79], [T80]. The grid model of a VLSI chip is quite simple. The chip is presumed to consist of a grid of vertical and horizontal *tracks* which are spaced apart by unit intervals. Processors are viewed as points and are located only at the intersection of grid tracks. Wires are routed through the tracks in order to connect pairs of processors. Although a wire in a horizontal track is allowed to cross a wire in a vertical track (without making an electrical connection), pairs of wires are not allowed to overlap for any distance or to overlap at corners (i.e., they cannot overlap in the same track). Further, wires are not allowed to overlap processors to which they are not linked. (The routing of wires in this fashion is also known as *layer per direction routing* and *Manhattan routing*.)

As an example, we have included a grid layout for the 8-node shuffle-exchange graph in Fig. 2. As before, the shuffle edges are drawn with solid lines while the exchange edges are drawn with dashed lines. Notice that we have omitted the self-loops in Fig. 2 since they are electrically redundant. In general, the processors need not all be placed on a single horizontal line (as they are in this example).

000   001 100 010   011 101 110   111

FIG. 2. *A grid model layout of the 8-node shuffle-exchange graph.*

Practical considerations dictate that the area of a VLSI layout be as small as possible. The *area of a layout* in the grid model is defined to be the product of the number of horizontal tracks and the number of vertical tracks which contain a processor or wire segment of the layout. For example, the layout in Fig. 2 has area 48. As can be easily observed, this is far from optimal.

2c. Thompson's layout. Given any k-bit string w, define the (Hamming) *weight* of w to be the number of 1-bits it contains. For example, the weight of 10110 is 3. Thompson's idea was to lay out the $N = 2^k$ nodes of the shuffle-exchange graph on a straight line in order of nondecreasing weight. It is easily seen that shuffle edges link nodes which have the same weight and that exchange edges link nodes which have weights differing by one. Thus the edges of such a layout are relatively short. In fact, nodes connected by shuffle edges can be placed in a group, so that only 2 horizontal tracks are used for all the shuffle connections. The remaining horizontal tracks are occupied by exchange edges.

The exchange eges are inserted from left to right so that each exchange edge occupies two vertical tracks and a portion of the lowest horizontal track which is empty at the time of its insertion. (For example, Fig. 2 displays a layout for the 8-node shuffle-exchange graph designed in this way.) This well-known strategy for inserting exchange edges guarantees that the number of horizontal tracks used will be minimal, and equal to the maximum number of edges which must (at some fixed point) overlap one another. Since exchange edges link nodes which differ in weight by one, it is easily seen that the maximum overlap is at most $O(\max_{0 \leq s \leq k} B_s)$ where B_s is the number of nodes of weight s.

It is easy to show that $B_s = C(k, s)$ for each s, where

$$C(k, s) = k!/[s!(k-s)!]$$

is the well-known function for binomial coefficients. It is also well known that $C(k, s)$ achieves its maximum value at $s = k/2$ for any k. Using standard asymptotic analysis, it is easily shown that $C(k, k/2) \sim (2/\pi)^{1/2}(2^k/k^{1/2})$ for large k. (For a good review of such techniques, see Bender and Orszag's book [BO78].) Thus Thompson's layout requires only $O(N/\log^{1/2} N)$ horizontal tracks. Since only 1 or 2 vertical tracks are needed to embed the vertical portions of the edges incident to any given node, we can conclude that Thompson's layout has area $O(N^2/\log^{1/2} N)$.

3. The complex plane diagram. In [HL80], Hoey and Leiserson observed that there is a very natural embedding of the shuffle-exchange graph in the complex plane. In what follows, we describe this embedding (which we call the *complex plane diagram*) and point out some of its more important properties.

3a. Definition. Let $\delta_k = e^{2\pi i/k}$ denote the kth primitive root of unity. Given any k-bit binary string $w = a_{k-1} \cdots a_0$, let $p(w)$ be the map which sends w to the point

$$p(w) = a_{k-1}\delta_k^{k-1} + \cdots + a_1\delta_k + a_0$$

in the complex plane. As each node of the $(N = 2^k)$-node shuffle-exchange graph corresponds to a k-bit binary string, it is possible to use the map to embed the shuffle-exchange graph in the complex plane. For example, we have done this for the 32-node shuffle-exchange graph (whence $k = 5$) in Fig. 3. For simplicity, each node is labeled with its value instead of its 5-bit binary string. (By the *value* of a node, we mean the numerical value of the associated k-bit binary string.)

3b. Properties. Examination of Fig. 3 indicates that the complex plane diagram has some very interesting properties. First, it is apparent that the shuffle edges occur in cycles (which we call *necklaces*) which are symmetrically placed about the origin.
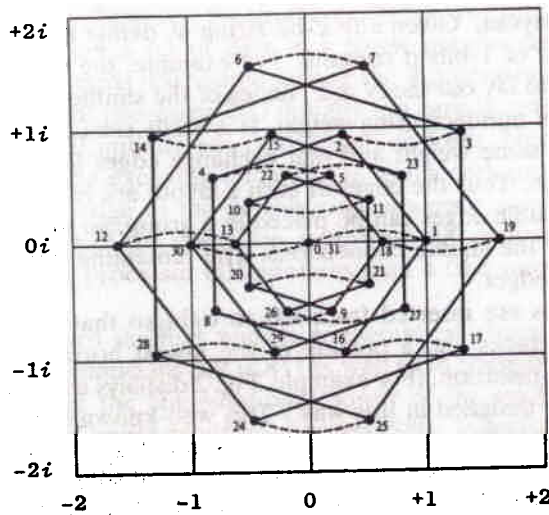

FIG. 3. *The complex plane diagram for the 32-node shuffle-exchange graph (taken from* [HL80]).

This phenomenon is easily explained by the following identity:

$$\delta_k p(a_{k-1} \cdots a_0) = a_{k-1}\delta_k^k + a_{k-2}\delta_k^{k-1} + \cdots + a_1\delta_k^2 + a_0\delta_k$$

$$= a_{k-2}\delta_k^{k-1} + \cdots + a_0\delta_k + a_{k-1}$$

$$= p(a_{k-2} \cdots a_0 a_{k-1}).$$

Thus traversal of a shuffle edge corresponds to a $2\pi/k$ rotation in the complex plane.

Except for degenerate cases, the preceding identity also indicates that each necklace is composed of k nodes, each a cyclic shift of the other. (Two nodes which are cyclic shifts of each other are also known as *conjugates*.) Such necklaces are called *full necklaces*. *Degenerate necklaces* contain fewer than k nodes and, because they must have some symmetry, are mapped entirely to the origin of the complex plane diagram. For example, {00000} and {0101, 1010} are degenerate necklaces while both {101, 011, 110} and {11100, 11001, 10011, 00111, 01110} are full. As we note in the following proposition, the number of degenerate necklaces is quite small compared to the number of full necklaces.

PROPOSITION 1. *There are $O(N^{1/2})$ degenerate necklaces and $N/\log N - O(N^{1/2}/\log N)$ full necklaces in the N-node shuffle-exchange graph.*

Proof. A node w is in a degenerate necklace if its binary representation has a nontrivial symmetry with respect to cyclic shifts. Without loss of generality, such a string of bits must consist of a block of k/p bits which is repeated p times where p is some prime divisor of k. As there are $2^{k/p}$ binary strings of length k/p, this means that the number of nodes in degenerate necklaces is at most

$$\sum_{\substack{p|k \\ p \geq 2}} 2^{k/p} \leq O(N^{1/2}).$$

The remaining $N - O(N^{1/2})$ nodes are in full necklaces. As each full necklace contains $\log N$ nodes, there are $N/\log N - O(N^{1/2}/\log N)$ full necklaces. $\square$

It will often be convenient to refer to a necklace by one of its nodes. In particular, we will use the notation $\langle w \rangle$ to indicate the *necklace generated by w*. This is simply

the collection of cyclic shifts of w. For example, the necklace generated by 101 is $\langle 101 \rangle = \{101, 011, 110\}$.

Exchange edges are also embedded in a very regular fashion by the complex plane diagram. In fact, each exchange edge is embedded as a horizontal line segment of unit length. This phenomenon is explained by the identity

$$p(a_{k-1} \cdots a_1 0) + 1 = a_{k-1}\delta_k^{k-1} + \cdots + a_1\delta_k + 1 = p(a_{k-1} \cdots a_1 1).$$

In some cases, several exchange edges are contained in the same horizontal line of the diagram. Such lines are called *levels*. For example, there are 9 levels in the diagram of the 32-node shuffle-exchange graph shown in Fig. 3. We will use the properties of levels to find $O(N^2/\log^{3/2} N)$-area layouts for the N-node shuffle-exchange graph.

4. Layouts based on the complex plane diagram. In this section, we present several layouts of the shuffle-exchange graph which are based on the complex plane diagram. We commence with a straightforward $O(N^2/\log N)$-area layout of the N-node shuffle-exchange graph. This layout has been discovered by many researchers (including Hoey and Leierson). Later, we show how the layout can be modified so as to require only $O(N^2/\log^{3/2} N)$ area.

4a. A straightforward $O(N^2/\log N)$-area layout. In what follows, we describe a straightforward layout of the shuffle-exchange graph which requires only $O(N^2/\log N)$ area. The layout is formed from a grid of levels and necklaces which we call the *level-necklace grid*. Each row of the grid corresponds to a level of the complex plane diagram. The columns of the grid are divided into consecutive column pairs, each pair corresponding to a necklace. The leftmost column of each column pair corresponds to that part of the necklace which is contained in the left half of the complex plane. Similarly, the rightmost column of each pair corresponds to the part of the necklace contained in the right half of the complex plane.

The rows of the level-necklace grid must have the same top-to-bottom order as do the corresponding levels in the complex plane diagram. The columns, however, may be arranged arbitrarily (provided that columns corresponding to the same necklace are adjacent in the grid).

Each node of the shuffle-exchange graph is placed at the intersection of the row and column of the grid that corresponds to the level and part of the necklace (left half or right half) to which it belongs in the complex plane diagram. For example, we have done this for a random ordering of the necklaces of the 32-node shuffle-exchange graph in Fig. 4. (Notice that we have used just one column each for the degenerate necklaces $\langle 0 \rangle$ and $\langle 31 \rangle$ since they each contain just one node. In general two columns will be required for necklaces which are mapped to the origin of the complex plane diagram, but the nodes of each such necklace should still be lumped together at a single point of the level-necklace grid.)

Given a level-necklace grid for a shuffle-exchange graph, it is not difficult to produce a layout for the graph. The main step is to partition the exchange edges in each row of the grid into nonoverlapping subsets. Each subset can then be assigned to a horizontal track of the layout. Except for the row corresponding to the real line in the complex plane diagram, the assignment of subsets to horizontal tracks within a row is arbitrary. (The assignment of horizontal tracks containing nodes on the real line must preserve the cyclic orientation of the nodes which are in necklaces that are mapped to the origin.)
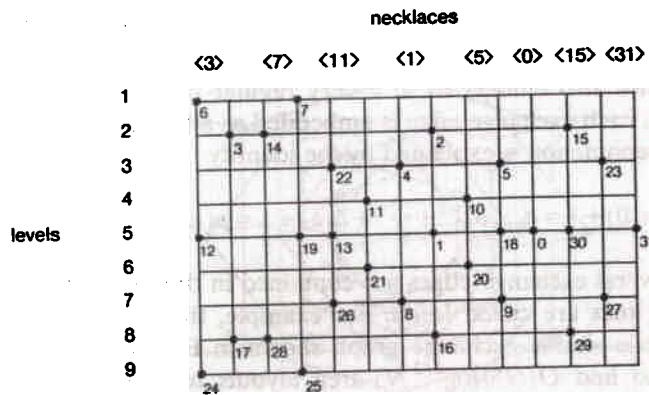

FIG. 4. *A level-necklace grid for the 32-node shuffle-exchange graph.*

Once this is done, the exchange edges can be inserted in the horizontal tracks and the shuffle edges can be inserted in the vertical tracks. (To be precise, some of the shuffle edges also occupy part of a horizontal track at the top or bottom of the layout.) By Proposition 1, the number of vertical tracks occupied by the necklaces is at most $2N/\log N + O(N^{1/2})$. Since there are precisely $N/2$ exchange edges, at most $N/2 + 2$ horizontal tracks are contained in the layout. Thus the total area of the layout of the N-node shuffle-exchange graph is at most $N^2/\log N + O(N^{3/2})$. As an example, we have displayed in Fig. 5 a layout of the 32-node shuffle-exchange graph produced from the level-necklace grid in Fig. 4.

4b. An improved $O(N^2/\log^{3/2} N)$-area layout. It is possible to improve the layout described in § 4a by reducing the number of horizontal tracks needed to embed the

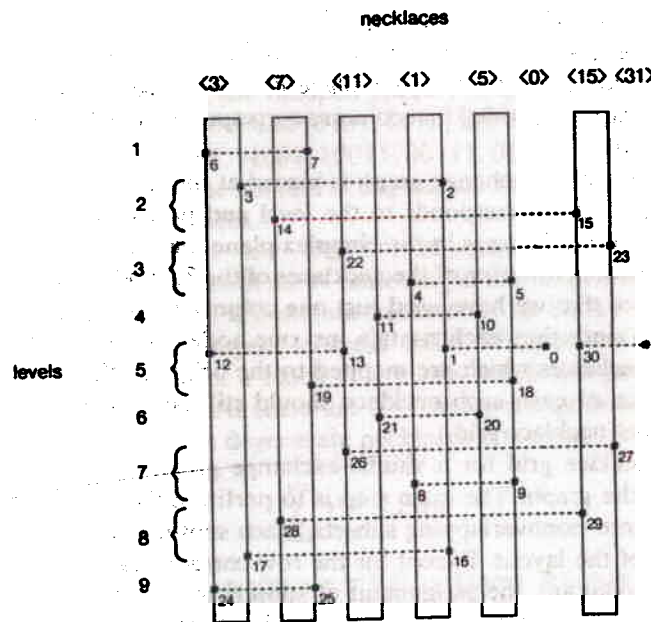

FIG 5. *Layout of the 32-node shuffle-exchange graph produced from the level-necklace grid shown in Fig. 4.*

exchange edges. This can be done by reordering the necklaces from left to right so as to increase the average number of exchange edges which can be inserted on each horizontal track. For example, the ordering of the necklaces shown in Fig. 6 results in far fewer horizontal tracks being used than did the ordering of necklaces shown in Fig. 5.

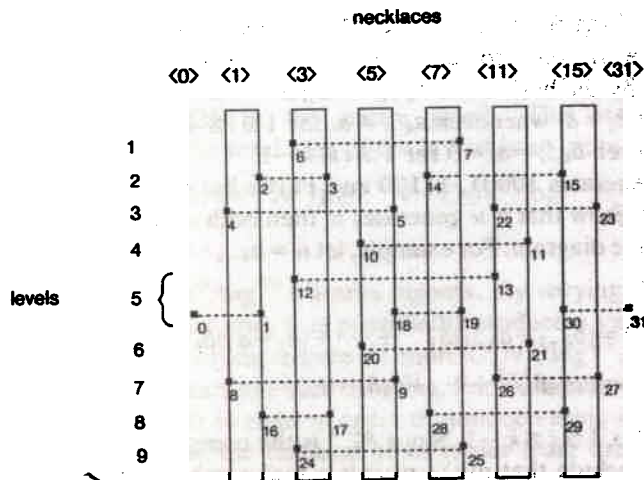

FIG. 6. *An improved layout for the 32-node shuffle-exchange graph.*

Although we do not know how to best order the necklaces in general, we have found several orderings which yield $O(N^2/\log^{3/2} N)$-area layouts for the N-node shuffle-exchange graph. For instance, we will show in what follows that such a layout can be constructed by arranging the necklaces from left to right in order of nondecreasing weight. (The *weight* of a necklace is simply defined to be the weight of any of its nodes.) As an example, the layout displayed in Fig. 6 is of this form. (This observation has also been made by Steinberg and Rodeh in [SR81].)

In order to bound the number of horizontal tracks needed to insert the exchange edges, we will show that the maximum overlap of exchange edges *on each level* is at most the number of nodes of size $h = \lfloor (k-1)/2 \rfloor$ on that level. Since the maximum overlap of exchange edges on each level is an upper bound on the number of horizontal tracks needed to insert the exchange edges on that level, we can thus conclude that the total number of horizontal tracks needed to insert all of the exchange edges is at most

$$B_h \le B_{k/2} = (2/\pi)^{1/2} N/\log^{1/2} N + O(N/\log^{3/2} N) \text{ where } N = 2^k.$$

Thus the resulting layout will have area at most

$$2(2/\pi)^{1/2} N^2/\log^{3/2} N + O(N^2/\log^{5/2} N).$$

Although it is clear the maximum *total* overlap (over all levels) of exchange edges is at most $B_{k/2}$, this is not sufficient to prove the result since any layout must also preserve the top-to-bottom partial order induced by the necklace structure on the exchange edges. It is only within individual levels that the top-to-bottom ordering of exchange edges is arbitrary. (As we noted earlier, some minor precautions are necessary

for the level corresponding to the real line.) It is *not* immediately clear, however, why the maximum overlap on each level is at most the number of nodes of size $h \leq k/2$ on that level. In what follows, we establish this result by breaking up each level into sublevels (for which the analysis is easier) and showing that the maximum overlap on each sublevel is at most the number of nodes of size h on that sublevel. The analysis requires some additional notation.

Consider a node of the form $a_{k-1} \cdots a_1 0$ for which either $a_{k-i} = 0$ or $a_i = 0$ or both for each $i \leq k$. We will refer to such a node as a *basis node*. A node $b_{k-1} \cdots b_0$ is said to be *generated* by the basis node $a_{k-1} \cdots a_0$ if

   1) $b_{k-i} = a_{k-i}$ and $b_i = a_i$ whenever $a_{k-i} \neq a_i$ for $1 \leq i \leq k-1$, and
   2) $b_{k-i} = b_i$ whenever $a_{k-i} = a_i = 0$ for $1 \leq i \leq k-1$.

For example, 10000 generates 10001, 11100 and 11101 but not 11111.

It is not difficult to show that if u generates v, then both u and v are on the same level of the complex plane diagram. For example, let $u = a_{k-1} \cdots a_0$ and $v = b_{k-1} \cdots b_0$ and observe that

$$p(v) - p(u) = (b_{k-1} - a_{k-1})\delta_k^{k-1} + \cdots + (b_1 - a_1)\delta_k + (b_0 - a_0)$$

$$= c_{k-1}\delta_k^{k-1} + \cdots + c_1\delta_k + c_0,$$

where $c_{k-i} = c_i$ for each i, $1 \leq i \leq k-1$. Since δ_k^{k-i} is the complex conjugate of δ_k^i for $1 \leq i \leq k-1$, we can conclude that $p(v) - p(u)$ is a real number and thus that u and v are in the same level of the complex plane diagram.

It is also easy to show that each node of the shuffle-exchange graph is generated by a unique basis node. In particular, the node which generates $b_{k-1} \cdots b_0$ can be found by

   1) setting $b_0 = 0$ and (if k is even) setting $b_{k/2} = 0$, and
   2) setting $b_i = b_{k-i} = 0$ for each i such that (originally) $b_i = b_{k-i} = 1$.

Since exchange edges link nodes which have the same basis node, we can conclude from the preceding arguments that it is possible to partition each level of the complex plane diagram into *sublevels* so that the nodes in each sublevel are precisely the nodes generated by some basis node. We will now show that the maximum overlap on each sublevel is at most the number of nodes of weight h on that sublevel.

Since the necklaces have been arranged from left to right in order of nondecreasing weight, the overlap of exchange edges between two nodes of weight s in any sublevel is at most $O(\max_{0 \leq s \leq k} B_s^*)$ where B_s^* is the number of nodes in that sublevel with weight s. In the following proposition, we compute B_s^* and show that its maximum for any sublevel occurs at $s = h$.

PROPOSITION 2. *Each basis node of weight r generates B_s^* nodes of weight s, where*

   1) $B_s^* = C(h-r, i)$ *for $s = r + 2i$ and $i \leq h - r$, and*
   2) $B_s^* = C(h-r, i)$ *for $s = r + 2i + 1$ and $i \leq h - r$*

when k is odd, and

   1) $B_s^* = C(h-r+1, i)$ *for $s = r + 2i$ and $i \leq h - r + 1$, and*
   2) $B_s^* = 2C(h-r, i)$ *for $s = r + 2i + 1$ and $i \leq h - r$*

when k is even.

Proof. When k is odd, there are precisely $h - r$ pairs $a_j = a_{k-j} = 0$ in a basis node of weight r. In order to generate a string of weight $s = r + 2i$ when k is odd, we must set $b_0 = 0$ and set i of the $h - r$ pairs so that $b_j = b_{k-j} = 1$. There are $C(h-r, i)$ such strings. To generate a string of weight $s = r + 2i + 1$ when k is odd, we must set $b_0 = 1$ and choose i of the $h - r$ pairs so that $b_j = b_{k-j} = 1$. As before, there are $C(h-r, i)$ such strings.

When k is even, there is also the degenerate pair $a_{k/2} = 0$. To generate a string of weight $s = r + 2i$ when k is even, we must choose i of the $h - r + 1$ pairs so that $b_j = b_{k-j} = 1$ (this count includes the "pair" $b_0 = b_{k/2} = 1$). There are $C(h - r + 1, i)$ such strings. To generate a string of weight $s = r + 2i + 1$ when k is even, we must set either $b_0 = 1$ and $b_{k/2} = 0$ or $b_0 = 0$ and $b_{k/2} = 1$, and choose i of the $h - r$ pairs so that $b_j = b_{k-j} = 1$ ($j \neq k/2$). There are $2C(h - r, i)$ such strings. □

Given Proposition 2, it is easily checked that the maximum value of B_r^s for any sublevel (independent of the value of r) occurs when $s = h$. Thus the sum (over all sublevels) of the maximum overlap at each sublevel is at most the number of nodes of weight $h = \lfloor (k-1)/2 \rfloor$ in the entire graph. This is at most $C(k, k/2) \sim (2/\pi)^{1/2}(2^k/k^{1/2})$. Thus the total area of the layout is no more than

$$2(2/\pi)^{1/2}N^2/\log^{3/2} N + O(N^2/\log^{5/2} N),$$

as claimed.

4c. Additional $O(N^2/\log^{3/2} N)$-area layouts. By varying the order of the necklaces in the level-necklace grid, it is possible to produce a variety of layouts for the shuffle-exchange graph which require at most $O(N^2/\log^{3/2} N)$ area. The complex plane diagram itself suggests one such ordering. For example, consider an arrangement of the necklaces from left to right in order of nondecreasing radius. (The *radius* of a necklace is defined to be the distance of its nodes from the origin in the complex plane diagram.) Such a layout corresponds to a folding of the complex plane diagram along its imaginary axis followed by a straightening of the necklaces. In what follows, we will show that, like a layout by necklace weight, a layout by necklace radius has area $O(N^2/\log^{3/2} N)$.

Because the layout by radius is so closely related to the complex plane diagram, our analysis will center on the complex plane diagram itself. As before, we will partition the levels into sublevels and find an upper bound on the maximum overlap of exchange edges on each sublevel separately. The number of horizontal tracks needed to insert the exchange edges will then be at most the sum of these upper bounds. We will show that this sum is at most $O(N/\log^{1/2} N)$.

Notice that the maximum overlap of exchange edges on a sublevel of the level-necklace grid is at most twice the maximum overlap on that sublevel in the complex plane diagram. (The factor of two is introduced by the "folding" of the diagram along its imaginary axis. Although straightening the necklaces might affect the maximum *total* overlap of exchange edges, it does *not* affect the overlap *within* a sublevel.)

Within a sublevel, an exchange edge can be identified by the real part of its midpoint. For example, the real part of the midpoint of exchange edge $(b_{k-1} \cdots b_1 0, b_{k-1} \cdots b_1 1)$ is

$$b_{k-1} \cos[2\pi(k-1)/k] + \cdots + b_1 \cos[2\pi/k] + \tfrac{1}{2}.$$

If a is a basis node of a sublevel, then a generates the other nodes in that sublevel by substitution of the appropriate pairs of ones. For instance, we may set $b_i = b_{k-i} = 1$, if $a_i = a_{k-i} = 0$. Let

$$T_a = \{1 \leq j \leq h \mid a_j = a_{k-j} = 0\}$$

denote those indices $1 \leq i \leq h$ where a pair of 1-bits may be substituted for a pair of 0-bits. (As before, $h = \lfloor (k-1)/2 \rfloor$ but for convenience, we shall henceforth assume that k is odd.) Notice that if b is generated by a, then the real part of the midpoint

of the exchange edge incident to b is

$$\sum_{1 \leq i \leq h}^{i \in T_a} 2b_i \cos (2\pi i/k) + \sum_{1 \leq i \leq h}^{i \notin T_a} \cos (2\pi i/k) + \tfrac{1}{2}.$$

We now introduce a random variable Z_a, which has as its image, all of the real parts of the midpoints of edges in the sublevel generated by a. Since $b_i = b_{k-i}$ can be either 0 or 1 when $i \in T_a$, let B_i be a random variable representing this choice. In particular,

$$B_i = 0 \quad \text{with probability } \tfrac{1}{2}, \quad \text{and}$$

$$B_i = 1 \quad \text{with probability } \tfrac{1}{2}.$$

Then

$$Z_a = \sum^{i \in T_a} 2 \cos (2\pi i/k)B_i + \sum_{1 \leq i \leq h}^{i \notin T_a} \cos (2\pi i/k) + \tfrac{1}{2}$$

$$= \sum^{i \in T_a} 2 \cos (2\pi i/k)(B_i - \tfrac{1}{2}).$$

Since the exchange edges have unit length in the complex plane diagram, two edges overlap if and only if their midpoints are within unit distance of each other. Thus the number of edges which overlap at position x on the sublevel generated by a node a is given by the formula

$$2^{|T_a|} \operatorname{Prob}\left[x - \tfrac{1}{2} \leq Z_a \leq x + \tfrac{1}{2}\right],$$

where $|T_a|$ denotes the cardinality of T_a. (We caution the reader that the notation $|x|$ is also used to denote the *absolute value* of x.)

Although the distribution function of Z_a is difficult to analyze directly, it does behave like a normal distribution. This is because Z_a is the sum of independent random variables which have mean 0 and variance $\sigma_i^2 = \cos^2 (2\pi i/k)$. The Berry–Esseen theorem states precisely how far Z_a can vary from a normal distribution. (For a proof of this theorem see [F71].)

BERRY–ESSEEN THEOREM. *Let $X_1, X_2, \cdots, X_m$ be independent random variables such that $\mathrm{E}(X_i) = 0$, $\mathrm{E}(X_i^2) = \sigma_i^2$, and $\mathrm{E}(|X_i^3|) = \rho_i$ for $1 \leq i \leq m$. Set $s^2 = \sigma_1^2 + \cdots + \sigma_m^2$ and $r = \rho_1 + \cdots + \rho_m$. In addition, let F denote the cumulative distribution function of the sum $(X_1 + \cdots + X_m)/s$. Then for all x,*

$$|F(x) - \Phi(x)| \leq 6r/s^3$$

where Φ is the standard normal cumulative distribution function.

In the case of a sublevel generated by a node a, we have

$$X_i = 2 \cos (2\pi i/k)(B_i - \tfrac{1}{2}) \text{ for } i \in T_a,$$

$$s_a^2 = \sum^{i \in T_a} \cos^2 (2\pi i/k),$$

$$r_a = \sum^{i \in T_a} |\cos^3 (2\pi i/k)|.$$

Applying the Berry–Esseen theorem, we can thus conclude that

$$\operatorname{Prob}\left[x - \tfrac{1}{2} \leq Z_a \leq x + \tfrac{1}{2}\right] = \operatorname{Prob}\left[(x - \tfrac{1}{2})/s_a \leq Z_a/s_a \leq (x + \tfrac{1}{2})/s_a\right]$$

$$\leq \Phi[(x + \tfrac{1}{2})/s_a] - \Phi[(x - \tfrac{1}{2})/s_a] + 12r_a/s_a^3.$$

Because the standard normal density function is symmetric and unimodal, we can conclude that the maximum of Prob $[x - \frac{1}{2} \leq Z_a \leq x + \frac{1}{2}]$ occurs at $x = 0$ and is at most $O(1/s_a + r_a/s_a^3)$.

In the following proposition, we find bounds for the values of r_a and s_a.

PROPOSITION 3. *For any basis node a*

$$r_a = \sum^{i \in T_a} |\cos^3 (2\pi i/k)| \leq |T_a|,$$

$$s_a^2 = \sum^{i \in T_a} \cos^2 (2\pi i/k) \geq \Omega(|T_a|^3/k^2).$$

Proof. The bound on r_a is easy to compute since $|\cos^3 (2\pi i/k)| \leq 1$. The calculation of s_a is a bit more tedious. In order to obtain a lower bound, $\cos^2 (2\pi i/k)$ must be made as small as possible. The smallest values occur when T_a contains indices i which are as close to $(k-1)/4$ as possible. In this case, we can approximate $\cos^2 (2\pi i/k)$ with the value $c(\pi/2 - 2\pi i/k)^2$, for some constant c. Direct computation reveals that the sum of these squares is at least $\Omega(|T_a|^3/k^2)$. □

Since $|T_a| < k$ for all a, we can conclude from the preceding that the maximum overlap of exchange edges on a sublevel generated by a is at most

$$O(2^{|T_a|} k^3/|T_a|^{7/2}).$$

Noting that there are precisely $C(h, j) 2^{h-j}$ sublevels generated by a node for which $|T_a| = j$ and summing, we can conclude that the total number of horizontal tracks needed to insert all of the exchange edges is at most

$$\sum_{j=1}^{h} C(h, j) 2^{h-j} O(2^j k^3/j^{7/2}) = O\left[k^3 2^h \sum_{j=1}^{h} C(h, j)/j^{7/2}\right].$$

It is not difficult to check that the dominant terms in the preceding sum occur when $j = h/2 \pm \Theta(h^{1/2} \log h)$. In this region, $j = \Theta(k)$ and thus the sum is bounded above by

$$O\left[2^h k^{-1/2} \sum_{j=1}^{h} C(h, j)\right] = O(2^{k-1}/k^{1/2}) = O(N/\log^{1/2} N),$$

thus completing the proof that a layout by necklace radius takes at most $O(N^2/\log^{3/2} N)$ area.

5. Remarks. It is worth remarking that the $O(N^2/\log^{3/2} N)$-area layouts for the shuffle-exchange graph described in § 4 actually require $\Omega(N^2/\log^{3/2} N)$ area and thus our analysis of these layouts cannot be improved by more than a constant factor. In each case, the lower bound on area can be derived from the fact that the maximum *total* overlap of exchange edges in the layouts is at least $\Omega(N/\log^{1/2} N)$. (Remember that although the maximum *total* overlap of exchange edges is *not* an *upper* bound on the number of horizontal tracks needed to insert the exchange edges, it *is* a lower bound.)

The $\Omega(N/\log^{1/2} N)$ lower bound on maximum overlap is easily established for the layout according to necklace weight since $\Omega(N/\log^{1/2} N)$ exchange edges link nodes of weight $k/2$ to nodes of weight $k/2 + 1$. The lower bound on maximum overlap is somewhat more difficult to prove for the layout according to necklace radius. The first step in the proof is to show that at least $N/2$ exchange edges are contained within a square of side length $ck^{1/2}$ centered at the origin of the complex plane diagram

(where c is a constant). (This can be done by using the techniques developed in § 4c). Next consider the sum (over i) of the total overlaps at points corresponding to radii of $i/2$ for $1 \leq i \leq ck^{1/2}$. Because the complex plane diagram is radially symmetric, it is possible to show that at least $\Omega(N)$ exchange edges are counted in this sum. Thus the overlap at one of these points must be at least $\Omega(N/k^{1/2}) = \Omega(N/\log^{1/2} N)$, as claimed.

Since Thompson [T80] has shown that any layout for the N-node shuffle-exchange graph must have area at least $\Omega(N^2/\log^2 N)$, we know that at least $\Omega(N/\log N)$ horizontal tracks are needed to insert the exchange edges for any ordering of necklaces in the level-necklace grid. However, there is no ordering of the necklaces known for which the exchange edges can be inserted using less than $o(N/\log^{1/2} N)$ horizontal tracks. This suggests an interesting open question since it would be nice to find an $O(N^2/\log^2 N)$-area layout based on the complex plane diagram. (Although an asymptotically optimal $O(N^2/\log^2 N)$-area layout for the shuffle-exchange graph has recently been found by Kleitman, Leighton, Lepley and Miller [KLLM81], it is rather complicated and of limited practical use.)

Although we do not know of necklace orderings for which the exchange edges can be inserted using less than $o(N/\log^{1/2} N)$ horizontal tracks, we *do* know of orderings for which the *maximum total overlap* of exchange edges is at most $O(N \log \log N/\log N)$. For example, an ordering of the necklaces by minimum value has a maximum total overlap of $\Theta(N \log \log N/\log N)$. (The *minimum value* of a necklace is simply the minimum of the values of the nodes contained in the necklace.)

Interestingly, an analysis of the minimum (over all orderings) of the maximum total overlap for small values of N indicates that there may always be an ordering for which the maximum total overlap is at most $O(N/\log N)$, the least possible. In fact, for $3 \leq N \leq 7$, this minimum maximum overlap is precisely $\lfloor (2^k - 2)/k \rfloor$. A summary of the minimum maximum overlap data for small values of N is included in Table 1.

TABLE 1
Maximum overlap of best known orderings

k	N	maximum overlap of best known ordering	optimal?
3	8	2	yes
4	16	3	yes
5	32	6	yes
6	64	10	yes
7	128	18	yes
8	256	33	yes
9	512	62	?
10	1024	115	?
11	2048	214	?
12	4096	388	?
13	8192	754	?

In addition to varying the order of the necklaces, improvements in the layout may also be made by rearranging the level assignments of the exchange edges. For example, the layout of the 32-node shuffle-exchange graph shown in Fig. 7 was constructed in this way. (The careful reader will notice that we have also manipulated the necklaces somewhat in order to produce this layout.) For a more detailed discussion

of the manner in which exchange edges can be reassigned, we refer the reader to [LM81]. (Such layouts have also been used in conjunction with the Blue Chip Project at Purdue [S81].)

FIG. 7. *An improved layout for the 32-node shuffle-exchange graph.*
